Preface

The evolution of mobile communication systems from the first to the fifth generation (5G) has revolutionized many aspects of society in the past four decades. Wireless networking technologies have become closely integrated with various activities in industry, business, entertainment, and daily life. With improved reliability and increased connection density, wireless networks have been attracting enterprise users, in addition to conventional mobile communication users, by supporting autonomous driving, factory automation, intelligent e-healthcare, smart city, and various other use cases.

Networking services have become highly heterogeneous and dynamic as we continuously integrate wireless networks into a wide variety of applications. Maturing wireless networking technology has attracted ever-increasing interests from multi-disciplines, including communications engineering, electrical and computer engineering, industry and system engineering, social science, economy, and operation management. Tremendous scientific and research efforts are currently aiming at the development of the next generation of heterogeneous, ubiquitous, energy-efficient, sustainable, reliable, and secure wireless networks.

Encyclopedia of Wireless Networks serves to provide comprehensive references to key concepts of wireless networks, including research results of historical significance, areas of current interests, and new directions for future wireless networks. The covered areas range from wireless networking technologies to applications, from the physical layer to the application layer, and from communications to computing in wireless network. This encyclopedia broadly addresses a large cross-section of current development and state-of-the-art technologies from more than 1000 researchers. Entries include descriptions of background, important definition, in-depth illustration, emerging applications, and bibliography. They are easily accessible with user-friendly online search and cross-reference.

The intended audience of this encyclopedia is broad and inclusive. It includes anyone concerned with wireless network technology and its relevant applications. It should be a valuable and authoritative reference for students, teachers, researchers, engineers, and practitioners who need a quick and authoritative reference to a subject in wireless networks and its relevant applications.

We would like sincerely thank the Editorial Board members and individual authors for their significant contribution to Encyclopedia. We also appreciate

Springer's editors and staff, including Susan Lagerstrom-Fife, Juby George, and Rukmani Parameswaran for their continuous support.

Finally, we hope the readers find this encyclopedia interesting and helpful. Any feedback to further improve the encyclopedia will be appreciated.

July 2020

List of Topics

5G Network

Section Editors: *Rahim Tafazolli and Rose Hu*

5G Wireless
Big Data in 5G
Cellular Unlicensed Spectrum Technology
Future Wireless Network Architecture
and Network Slicing
Hyper Cellular Network: Control-Traffic
Decoupled Radio Access Network
Architecture
Non-orthogonal Multiple Access
Sparse Code Multiple Access
Three-Dimensional Channel Measurement
for the Indoor 5G Multiuser Massive
MIMO System
Wireless Edge Caching
Wireless Fading Channel Model for
5G and Future

Ad hoc Network

Section Editor: *Cheng Li*

Asynchronous Coordination Techniques
Fingerprinting Localization
Hidden and Exposed Terminal Problems
Joint Network Coding and Opportunistic
Forwarding
Location Based Service of Ad Hoc Networks
Multiple Access Techniques
Network Coding-Aware Routing in Wireless
Ad Hoc Networks
Opportunistic Routing (OR)
Routing for Vehicular Ad Hoc Networks

Big Data for Networking

Section Editor: *Song Guo*

Big Data Networks
Big Network Data
Data-Driven Edge Computing
Data-Driven Mobile Social Networks
Data-Driven Network Control
Data-Driven Pattern Prediction
Data-Driven QoE Measurement
Data-Driven Resource Allocation
Data-Driven Security
Data-Driven Service Provisioning
Data-Driven Smart City
Industrial Big Data
Ubiquitous Big Data
Urban Big Data
Wireless Big Data

Cellular Network, 2G/3G Network, 4G/LTE Network

Section Editor: *Hsiao-Hwa Chen*

Analog and Digital Communications
Architectures, Key Techniques, and
Future Trends of Heterogeneous Cellular
Networks
Artificial Noise Schemes Based on MIMO
Technology in Secure Cellular Networks
Base Station Cooperations Under Imperfect
Conditions
Cellular Networks: An Evolution from 1G to 4G
Coordinated Multipoint Transmission
and Reception
Cyclic Prefix-Free OFDM/OFDMA Systems,
Design, and Implementation

Densification of Wireless Networks, from
 Few to Massive
 Deployment Strategies of Cellular Networks
 Efficient Beamforming Design for Cellular
 Networks with Energy-Constrained
 Devices
 Energy Efficiency of Cellular Networks
 Evolution of Vehicular Networks in the
 Transition from 3G to 4G Systems
 Fog Computing for Intelligent Mobile and
 IoT Networks
 Heterogeneous Small Cell Networks
 Key Technologies in 4G/LTE Network
 Machine Learning Paradigms in Wireless
 Network Association
 Mobile Edge Computing: Low Latency
 and High Reliability
 Multiple Access Technique for Cellular
 Wireless Networks
 Random Access Technology in Cellular
 Networks
 Reinforcement Learning-Based Wireless
 Communications Against Jamming
 and Interference
 Relay-Involved Device-to-Device
 Communications in LTE Networks
 Relaying in LTE-Advanced
 Resource Management in Macrocell–Small
 Cell Systems and D2D-Assisted Cellular
 Systems
 Security and Privacy in 4G/LTE Network
 Sidelink Transmissions and Proximity
 Services in LTE-A and Beyond
 Survey on Machine-Learning Techniques
 in LTE Networks
 The Primary Synchronization Sequences
 in LTE

Cognitive Radio Network

Section Editor: *Ning Zhang*

Cognitive Radio Sensor Networks
 Cognitive Radio-Based Non-orthogonal
 Multiple Access
 Cooperative Cognitive Radio Networks
 Database-Based Spectrum Access
 Dynamic Spectrum Access in Multiple
 Primary Networks

Dynamic Spectrum Access Through Cognitive
 Radio Networking
 Energy Harvesting Cognitive Radio Sensor
 Networks
 Game Theory-Assisted Cooperative Spectrum
 Access
 MAC in Cognitive Radio Networks
 Spectrum Resource Allocation in Cognitive
 Radio Networks
 Spectrum Sensing in Cognitive Radio Networks
 Spectrum Sensing with Power Recognition

Cooperative Communications

Section Editor: *Kaoru Ota*

Radio-on-Demand Wireless LAN

Data Center Network

Section Editor: *Lei Lei*

Bandwidth Allocation in Data Center Networks
 Data Center Network in Cloud Computing
 Data Center Network Virtualization
 Data Center Networking (DCN): Infrastructure
 and Operation
 Edge Data Centers in Fog Computing
 Load Balancing in Data Center Networks
 SDN-Enabled Data Center Networks
 Wireless Communication in Data Center

Delay Tolerant and Opportunistic Network

Section Editor: *Yuanguo Bi*

Contact Plan Design for Space Disruption/
 Delay-Tolerant Networks
 Data Dissemination in Delay Tolerant Networks
 with Geographic Information
 Distributed Community Detection in
 Opportunistic Networks
 Mobile Data Offloading via D2D-Assisted
 Communications in Wireless Networks
 Opportunistic Routing in Underwater Sensor
 Networks
 Security in Delay-Tolerant Networks

Equalization, Synchronization and Channel Estimation

Section Editor: *Yingying (Jennifer) Chen*

Equalization Techniques for Single-Carrier Modulations
 Fundamental Properties of Wireless Relays and Their Channel Estimation
 Interference Alignment in Wireless Networks
 Learning-Based Secure Mobile Offloading

Future Network Architecture

Section Editor: *Wei Quan*

Blockchain: Enabling Future Internet with Intrinsic Security
 Collaborative Multipath Transmission
 Computation Offloading in Mobile Edge Computing
 Information-Centric Networking: Basic Principle and Architecture
 Mobile Crowdsensing: Issues and Challenges
 Smart Identifier Network
 Universal Identifier-Based Network

Game Theory in Wireless Network

Section Editor: *Dusit Niyato*

Game Theoretic Modeling of Zero-Rating Internet Provisioning
 Matching Game for Load Distribution in Multi-tier Cellular Networks
 Robust Games for Power Control in Multi-tier Cellular Networks

Interference Characterization and Mitigation

Section Editor: *Lin Cai*

Capacity Analysis of Interference-Limited Wireless Networks in Three-Dimensional Space
 Interference Alignment for Power Line Communications
 Interference Characterization for Cooperative Communications in Mobile Ad Hoc Networks
 Interference-Aware Distributed Resource Allocation
 Interference-Aware Scheduling in Wireless Networks

Non-orthogonal Multiple Access (NOMA)
 Path Loss and Interference Analysis for a Random Two-Hop Relay Link
 Random Distance Distribution

Internet of Things

Section Editors: *Xiuzhen Cheng and Wei Cheng*

Applications and Architectures of Social Internet of Things
 Emerging Wireless Technologies for Internet of Things Applications: Opportunities and Challenges
 Internet of Things (IoT) Forensic Science
 Internet of Things: Architecture, Key Applications, and Security Impacts
 Maritime Internet of Vessels
 Situation Awareness in Smart Grids

Internet of Things and Its Applications

Section Editor: *Phone Lin*

Anomaly Detection for IoT Systems
 Conversational Chatbot for Disaster Information
 EV Charging Scheduling
 Machine-Type Communication
 Narrowband Internet of Things
 Neighborhood-Based ICT-Driven Support (NIS) System of Emergency Medical Services (EMS) for Elderly People in Hyper-Aged Societies
 Secure Device Pairing
 Social Internet of Things
 Social IoT Crowd-Sourcing on Disaster Reduction

Interworking Heterogeneous Wireless Network

Section Editor: *Ping Wang*

Area Spectral Efficiency of Ultradense Networks
 Cognitive Heterogeneous Networks
 Mobile Edge Caching in HetNets
 Network Selection in Heterogeneous Wireless Networks
 WiFi Offloading in WiFi-Cellular Networks

Medium Access Control

Section Editors: *Hassan Aboubakr Omar* and *Qiang Ye*

Adaptive Medium Access Control for
Internet-of-Things-Enabled
MANETs

Millimeter-wave Communications

Section Editor: *Ming Xiao*

Hybrid Precoding
Lens Antenna Array
Low-Latency Communications with
Millimeter Wave
Massive MIMO BDMA Transmission
Millimeter Wave Beam Training and
Tracking
Millimeter Wave Channel Access
Millimeter Wave Channel Measure
Millimeter Wave Channel Modeling
Millimeter Wave MAC Layer
Millimeter Wave Massive MIMO
Millimeter Wave NOMA
Millimeter Wave Security
Millimeter-Wave (mmWave) Multiple-Input
Multiple-Output (MIMO) Technique
Omnidirectional Transmission for Massive
MIMO
Per-Beam Synchronization for Millimeter-Wave
Massive MIMO
Pilot Reuse for Massive MIMO

MIMO-based Network

Section Editor: *Wei Zhang*

Cell-Free Massive MIMO
Index Modulation
Massive MIMO
Massive MIMO Channel Estimation
MIMO Detection
MIMO Relay
Network MIMO
Satellite MIMO
Space-Time Block Codes
Spatial Modulation

Mobility Management and Models

Section Editors: *Sandra Céspedes* and *Sangheon Park*

Distributed IP Mobility Management
Handoffs, Modeling in IP Networks
Handover in LTE-U/LAA
Mobile IP
Mobility Management in 5G
Mobility Management in NDN
Mobility Management with ID/Locator
Separation
Mobility in Multicast
Network-Layer Mobility Management
Proxy Mobile IPv6

Molecular, Biological and Multi-scale Communications

Section Editor: *Adam Noel*

Applications of Molecular Communication
Systems
Brain-Machine Interfaces
Brownian Motion
Channel Modeling of Microscale Terahertz
Communication
Communications and Networking in
Droplet-Based Microfluidic
Systems
Connectivity via Molecular Signaling
Drug Delivery via Nanomachines
Energy Modeling for Nanoscale Terahertz
Communication
Modeling Approaches for Simulating Molecular
Communications
Modulation in Molecular Signaling
Molecular Bit Detection
Molecular Event Detection
Nanonetworks
Nanoscale Terahertz Communications
Neuronal Communication Channels
Reaction-Diffusion Channels
Receiver Mechanisms for Synthetic
Molecular Communication Systems with
Diffusion
Synchronization of Nanomachines

Network Economics and pricing

Section Editors: *Jianwei Huang and Yuan Luo*

Auction
 Budget Feasible Mechanisms
 Collusion
 Dynamic Pricing
 Efficiency and Pareto Optimality
 Fairness
 Market Entry
 Matching for Cooperative Spectrum Sharing
 Network Effects
 Oligopoly Pricing in Wireless Networks
 Preferences and Utility Functions
 Prospect Theory for Communication Networks
 Sharing Economics

Network Forensics and surveillance, Fault Tolerance and Reliability

Section Editor: *Hongwei Li*

General Theory of Information Security
 Network Privacy Surveillance and Privacy Protection

Network Measurement and Virtualization

Section Editor: *Yusheng Ji*

Incentive Mechanism for Crowdsourcing-Based Spectrum Measurement
 Network Slicing-Enabled Green C-RAN
 Performance Modeling of Virtual Packet Forwarding Functions for Wireless Network Virtualization
 Resource Scheduling in Virtualized Wireless Networks

Quality of Service, Quality of Experience and Quality of Protection

Section Editors: *Rui L. Aguiar and Yu Cheng*

Long-Term Quality of Protection
 QoE Assessment Models
 QoS in Indoor Localization
 QoS-Aware MAC
 Quality of Service in IEEE 802.11 Networks
 Quality of Service of Wireless Sensor Networks Modeled by Ginibre Point Processes

Resource Allocation and Management

Section Editors: *Junshan Zhang and Nan Cheng*

Cache Placement and Content Delivery Design in Wireless Caching Networks
 Effective Utilization of Unlicensed Spectrum
 Incentive Mechanisms for Mobile Crowdsensing
 Media Access Control for Narrowband Internet of Things: A Survey
 Power Control for Data Transmission in Wireless Networks
 Power Control in Wireless Networks
 Resource Allocation in Industrial IoT
 Resource Allocation in NOMA-Assisted D2D Networks
 Resource Allocation in SDN/NFV-Enabled 5G Networks
 Resource Allocation in UAV-Aided Wireless Networks
 Social Group Utility Maximization

Routing and Multi-cast, Router and Switch Design

Section Editor: *F. Richard Yu*

Energy-Aware and Throughput-Improved Route Selection for Wireless Multi-hop Networks
 Enhancing QoE-Aware Wireless Edge Caching with Software-Defined Wireless Networks
 Handoff Management in Wireless Communication-Based Train Control Systems
 Heterogeneous Networks Through Multi-resources Deployment, Performance Enhancement for
 Integrated System of Networking, Caching, and Computing
 Interference Mitigation in Wireless Communications-Based Train Control (CBTC), Cognitive Control Approach
 Joint Caching, Computing, and Routing for Video Transcoding in Wireless Networks
 Mining Task Offloading in Wireless Blockchain Networks
 Mobile Content Distribution Architecture
 Offloading Delay-Tolerable Data Traffic to Connected Vehicle Networks

Secure Routing in Cognitive Radio Vehicular Ad Hoc Networks
 Topology Control in Mobile Ad Hoc Networks with Cooperative Communications
 Trust-Based Routing in Software-Defined Vehicular Ad Hoc Networks

Scaling Laws and Fundamental Limits

Section Editor: *Ning Lu*

Capacity of Wireless Ad Hoc Networks
 Network Information Theory
 Transmission Capacity

Security, Privacy and Trust

Section Editor: *Kui Ren*

Access Control
 Authentication
 Bluetooth Low Energy (BLE) Security and Privacy
 Byzantine Attack and Defense in Wireless Data Fusion
 Encrypted Search for Medical Data
 Flow Table Overflow Attacks
 IoT Security
 Mobile Security and Privacy
 Multimedia Security
 Privacy-Preserving Data Collection
 Private Truth Discovery in Cloud-Empowered Crowdsensing Systems
 Radio-Frequency Fingerprinting-Based Physical Layer Identification
 Vehicle Ad-Hoc Networks: Services, Security, and Privacy
 Verifiable Cloud Computing
 Wireless Key Establishment

Short Range Communications, RFID and NFC

Section Editor: *Zhiguo Shi*

Indoor Visible Light Communication Networks for Camera-Based Mobile Sensing
 Smart Device-to-Device Communication: Communication Establishment and Maintenance
 Wireless Charger Deployment with Communication Constraint

Smart Grid Communications

Section Editor: *Vincent Wong*

Advances in Distribution System Monitoring Architecture and Data Management for Smart Community Information Platform
 Cyber-physical Security in Smart Grid Communications
 Game Theory Meeting Vehicle-to-Grid Regulation: Past, Present, and Future
 Intelligence and Trading with Energy Storage and Renewable Generation of Microgrids
 Power Line Communications for Grid Discovery and Diagnostics
 Privacy-Preserving Data Aggregation for Smart Grids
 Smart Grid Communication Based on IEEE 2030 Standard
 Smart Metering, Specific Challenges, and Solution Approaches
 Ultra-reliable and Low-Latency Communications for the Smart Grid

Vehicular Network

Section Editors: *Lian Zhao and Qing Yang*

Delay-Tolerant Network Routing
 Vehicular Ad Hoc Network
 Wireless Access in Vehicular Environment

Video Streaming

Section Editor: *Zhi Liu*

Edge Computing for Real-Time Video Stream Analytics
 Live Video Streaming in Wireless P2P Networks
 QoE Measurement and Assessment of Video Streaming
 Quality of Experience for Wireless Video Streaming
 Scalable Video Streaming
 Video Streaming over Vehicular Networks
 Wireless Video Delivery
 Wireless Video Streaming

Wireless Body Area Network and e-healthcare

Section Editor: *Honggang Wang*

60 GHz in WBAN and mm-Wave Technologies
Data Analytics for Longitudinal Biomedical Data
Internet of Medical Things
Molecular Communication for Wireless Body Area Networks
Sleep Monitoring Using WiFi Signal
Turning Detection in Sandbar Sharks Through Accelerometer Data

Wireless Security

Section Editors: *Haojin Zhu and Jian Shen*

Automotive Security
Blockchain
Differential Privacy
Distributed Storage Security
Fault Tolerance and Reliability of Smart Grids
Group Key Agreement for Wireless Networks
Mixed Network
New Variants of Mirai and Analysis
Pilot Spoofing Attack
Privacy Game
Privacy Preservation for Location-Based Services
Trustworthiness Evaluation
Wi-Fi Protected Access (WPA)
Wireless Group Authentication
Wireless Jamming Attack

Wireless Sensor Network

Section Editors: *Jiming Chen and Ruilong Deng*

Application of Machine Learning in Wireless Sensor Network
Collaborative Beamforming in Wireless Sensor Networks

Cooperative Localization in Wireless Sensor Networks
Data Gathering in Wireless Sensor Networks
Energy Harvesting Sensor Node Scheduling in Wireless Sensor Networks
Energy Harvesting Technologies in Wireless Sensor Networks
Extending WSN Lifetime Based on Evolutionary Clustering Algorithm
Imprecise Computation Task Mapping on Multi-core Wireless Sensor Networks
Information-Centric Wireless Sensor Networks
Lattice Reduction and Its Applications in Wireless Sensors Network
Localization in 3D Surface Wireless Sensor Networks
Machine Learning in Wireless Sensor Networks for the Internet of Things
Middleware for Wireless Sensor Networks
Parameter Estimation Exploiting WSNs with Arbitrary Topology Geometry
Protocol Stack Architecture for Wireless Sensor Networks
Wireless Sensor Network Security
Wireless Sensor Networks Enabled Urban Traffic Management

WLAN and OFDM

Section Editor: *Xianbin Wang*

Frequency-Domain Equalization in OFDM and Single-Carrier Modulation
Index Modulation for OFDM
PAPR Reduction in OFDM Systems
Principle of OFDM and Multi-carrier Modulations
Time and Frequency Synchronization in OFDM Systems
Time-Domain Synchronous Orthogonal Frequency Division Multiplexing

About the Editors

Xuemin (Sherman) Shen (M'97–SM'02–F'09) received his Ph.D. degree in Electrical Engineering from Rutgers University, New Brunswick, NJ, USA, in 1990. Dr. Shen is currently a University Professor with the Department of Electrical and Computer Engineering, University of Waterloo, Canada. His research focuses on network resource management, wireless network security, Internet of Things, 5G and beyond, and vehicular ad hoc and sensor networks. Dr. Shen is a registered Professional Engineer of Ontario, Canada, an Engineering Institute of Canada Fellow, a Canadian Academy of Engineering Fellow, a Royal Society of Canada Fellow, a Chinese Academy of Engineering Foreign Fellow, and a Distinguished Lecturer of the IEEE Vehicular Technology Society and Communications Society.

Dr. Shen received the R.A. Fessenden Award in 2019 from IEEE, Canada, James Evans Avant Garde Award in 2018 from the IEEE Vehicular Technology Society, Joseph LoCicero Award in 2015, and Education Award in 2017 from the IEEE Communications Society. He has also received the Excellent Graduate Supervision Award in 2006 and Outstanding Performance Award five times from the University of Waterloo and the Premier's Research Excellence Award (PREA) in 2003 from the Province of Ontario, Canada. Dr. Shen served as the Technical Program Committee Chair/Co-Chair for the IEEE Globecom'16, the IEEE Infocom'14, the IEEE VTC'10 Fall, the IEEE Globecom'07, the Symposia Chair for the IEEE ICC'10, the Tutorial Chair for the IEEE VTC'11 Spring, and the Chair for the IEEE Communications Society Technical Committee on Wireless

Communications. He was the Editor-in-Chief of the *IEEE Internet of Things Journal* and the Vice President of Publications of the IEEE Communications Society.

Xiaodong Lin is a Ph.D. in Information Engineering from Beijing University of Posts and Telecommunications, China, and the Ph.D. (with Outstanding Achievement in Graduate Studies Award) in Electrical and Computer Engineering from the University of Waterloo, Canada. He is currently an associate professor in the School of Computer Science at the University of Guelph, Canada. Dr. Lin's research interests include computer and network security, computer forensics, privacy protection, applied cryptography, and software security. He is a Fellow of the IEEE.

Kuan Zhang (S'13-M'17) has been an assistant professor at the Department of Electrical and Computer Engineering, University of Nebraska-Lincoln, USA, since September 2017. He received his Ph.D. degree in Electrical and Computer Engineering from the University of Waterloo, Canada, in 2016. Dr. Zhang was also a postdoctoral fellow with the Broadband Communications Research (BBCR) group, Department of Electrical and Computer Engineering, University of Waterloo, Canada, from 2016 to 2017. His research interests include security and privacy for mobile social networks, e-healthcare, cloud/edge computing, and Internet of Things. Dr. Zhang received IEEE Technical Committee on Scalable Computing (TCSC) Award for Excellence – Outstanding Ph.D. Thesis – in 2017. He was the recipient of Best Paper Award in IEEE WCNC 2013, Securecomm 2016, and BigDataSE 2019.

A Securing Routing Scheme for Vehicular Networks with Cognitive Radios

► [Secure Routing in Cognitive Radio Vehicular Ad Hoc Networks](#)

Access Control

Kan Yang
Department of Computer Science, The
University of Memphis, Memphis, TN, USA

Key Applications

Any data or system applications

Definition

In the field of information security, access control (AC) is the selective restriction of access to a resource (e.g., data, system, application, etc.).

Access Control Models

Access control is an effective approach to guarantee confidentiality and privacy of the resource.

Figure 1 shows the history of access control models: access control lists, role-based access control, and attribute-based access control.

Access Control Lists

Access control lists (ACLs) are the most basic model of access control, where each data is associated a list of mappings between the set of entities and the set of actions that each entity can take on the data. For example, the home address can be accessed by operators (read only), markets (read only), and utility service providers (read, modify, and delete). Some grid status can only be accessed by power control centers. Whenever a user tries to perform any action (e.g., modify) on the data (e.g., home address), the system or server checks the ACL of this data and determines whether to allow this action for that user. The ACLs can also be applied for a group of data (e.g., account information: name, home address, contact information), which may have the same mappings between actions and entities.

The major limitation of ACL model is that every user is treated as a distinct entity with distinct sets of privileges for each data. That means ACLs have to be defined separately for each data (or group of data), which would be a cumbersome process when many users have different levels of access permissions to a large amount of data. It is time-consuming and error-prone to selectively add, delete, and change ACLs on individual data or even group of data.

Access Control, Fig. 1 Access control models (Yang et al. 2016)

Role-Based Access Control

Role-based access control (RBAC) (Ferraiolo et al. 2001; Sandhu et al. 1996) determines whether access will be granted or denied based on user's role or function. Since many people may have the same role (e.g., market researcher), RBAC may group them into one category with a particular role, which means that the access control permission on a particular data can be set only once for all members in the group with the same role. Users can also be members of multiple groups which may have different access permissions, where more restrictive permissions override general permissions in RBAC.

Although RBAC has many advantages compared with ACL model, it still suffers from some limitations. One of the most important is that it is difficult to achieve the fine-grained access control for each user when grouping them into categories based on roles. So, how to differentiate individual members of a group is a challenging problem in RBAC.

Attribute-Based Access Control

In order to define specific access permissions for individual users, attribute-based access control (ABAC) is proposed to control data access based on the attributes associated with the user. According to the definition of NIST (Hu et al. 2014), in ABAC, the access policy is defined based on both subject attributes and object attributes under some environmental conditions. ABAC is more flexible in defining access policies than RBAC.

A key advantage of ABAC model is that no specific users are needed to be known in advance when defining access policies. The access can be granted as long as the attributes of users can satisfy access policies. Thus, ABAC is useful for the applications where organizations or data owners allow unanticipated users to be able to access the data if their attributes can satisfy some policies. This feature makes ABAC well suitable for large enterprises. An ABAC system can implement existing role-based access control policies and can support a migration from role-based to a more granular access policy based on many different attributes of individual users. Gartner predicts that "By 2020, 70% of all businesses will use ABAC as the dominant mechanism to protect critical assets, up from 5% today (in 2013)."

Encryption-Based Implementation

The ACLs, RBAC, and ABAC all require the system/server to evaluate access rules/policies and make access decisions. When the server is not fully trusted by data owners, e.g., cloud servers, how to protect data confidentiality and privacy becomes a challenging problem. In order to cope with this challenge, cryptographic techniques are applied to implement the abovementioned three access control models. Data owners encrypt files by using the symmetric encryption approach with content keys and then use every user's public key to encrypt the content keys. However, traditional public key encryption methods may pro-

duce many copies of ciphertexts for multiple users, which is not efficient in large-scale systems, e.g., smart grid. Moreover, the key management is also a complex issue in public key infrastructures (PKI).

To eliminate the need for distributing public keys (or maintaining a certificate directory), identity-based encryption (IBE) (Boneh and Franklin 2001) is a new cryptographic primitive that allows data owners to encrypt their data with identities of users instead of their public keys. To make access policies more flexible and expressive, attribute-based encryption (ABE) (Goyal et al. 2006; Bethencourt et al. 2007) is proposed for access control of encrypted data. There are two complimentary forms of ABE, namely, key-policy ABE (KP-ABE) (Goyal et al. 2006) and ciphertext-policy ABE (CP-ABE) (Bethencourt et al. 2007). In KP-ABE systems, keys are associated with access policies, and ciphertext is associated with a set of attributes, while in CP-ABE systems, keys are associated with a set of attributes, and ciphertext is associated with access policies.

Synonyms

Adaptive channel access control; Contention-Based and Contention-Free Channel Access; Distributed transmission coordination; QoS-aware hybrid medium access control (MAC)

Definitions

Adaptive medium access control (MAC) for Internet-of-Things (IoT)-based ad hoc networking refers to a distributed (infrastructure-less) link-layer mechanism to coordinate channel access for data transmissions from a varying number of IoT devices, generating either delay-sensitive services or data-hungry applications. The adaptive MAC should achieve and maintain high performance for heterogeneous services with differentiated quality-of-service (QoS) requirements (e.g., delay and throughput) in network traffic load dynamics.

Background and Key Applications

Next-generation wireless networks are envisioned to interconnect a proliferation of Internet-of-Things (IoT) devices (e.g., smartphones, smart sensors and actuators, home appliances) to achieve seamless communication interaction and diversified service customization, such as smart cities, industrial automation, and intelligent

transportation (Gubbi et al. 2013). To support an increasing number of end devices, current communication infrastructures are required to be boosted extensively with additional installation and operational cost. In the scenarios where the network infrastructures are temporarily not in place or not accessible (e.g., in hotspot areas or postdisaster areas), mobile ad hoc networking is an infrastructure-less and cost-effective networking technology to connect a large number of IoT devices via a device-to-device (D2D) communication mode (Nishiyama et al. 2015). In mobile ad hoc networks (MANETs), nodes are self-organized and initiate transmission requests over a common wireless channel (with 20MHz bandwidth at 2.4GHz or 5.9GHz spectrum frequencies) in a distributed way. To achieve consistently high link-layer performance (low packet transmission delay and high data throughput), an efficient medium access control (MAC) mechanism is required to coordinate channel access from a group of end devices by adapting to the variation of network traffic load (Natkaniec et al. 2013).

Without relying on centralized transmission coordination and device synchronization, the carrier sensing multiple access with collision avoidance (CSMA/CA)-based IEEE 802.11 distributed coordination function (DCF) (Bianchi 2000) is the most commonly used MAC scheme in existing MANETs, where packet transmissions from each node are initiated based on channel contention with an exponential backoff mechanism employed for collision avoidance. The contention-based DCF has the advantage of simplified implementation and high channel utilization in low traffic load conditions (i.e., the number of devices is low). However, its performance degrades substantially when the number of nodes becomes high, since a large portion of channel time is wasted in collided packet transmissions and collision resolution. Distributed time division multiple access (TDMA) schemes (Kanzaki et al. 2003; Wilson et al. 1993) eliminate transmission collisions by allocating time slot(s) exclusively for each device and thus achieve high resource utilization in high network load

conditions. However, the control information exchange among devices for distributed time slot acquisition makes the performance of TDMA inferior to DCF in a low network condition. Due to the performance trade-off between contention-based MAC and reservation-based time slot allocation, hybrid MAC schemes are proposed to combine the advantages of both types of MAC schemes by switching between contention-based and contention-free MAC frame structures, either periodically (Zhang et al. 2010, 2011) or adaptively based on instantaneous network load conditions (Hu et al. 2011). For most existing hybrid MAC schemes, the MAC switching decision is made upon measurement of some MAC parameters (e.g., number of idle TDMA slots (Ahmed 1997), number of lost acknowledgments (ACKs) (Hu et al. 2011), node buffer occupancy (Doerr et al. 2005)) which reflect the current network load condition. However, it is difficult to establish an analytical model between those measurement parameters and certain performance metrics (e.g., network throughput and packet delay), thus making the MAC switching decisions not optimal.

To satisfy differentiated quality-of-service (QoS) requirements from heterogeneous IoT services, the distributed MAC is expected to be both context-aware and service-aware (or QoS-aware) in a changing network environment. For example, delay-sensitive voice communications and remote control applications have stringent delay bound requirements on each transmitted packet so that the packets that are received beyond the delay bound are dropped, whereas the smart sensing applications collect data from a massive number of end devices which are throughput-oriented. Service prioritized contention schemes (e.g., busy tone-based MAC (Wang et al. 2007)) give guaranteed channel access opportunities to voice devices to relieve their contention collisions with data devices, which, on the other hand, suppress the data traffic channel access probability. Moreover, packet collisions among voice devices exist and are accumulated with the increase of voice device number. Existing distributed TDMA mechanisms can alleviate channel contention collisions but

are not suitable for supporting heterogeneous services. Since most of the data-hungry sensing applications generate event-driven data traffic, the allocated time slots can be underutilized and need to be adaptive to traffic burstiness. To meet differentiated QoS demands, an adaptive and QoS-aware hybrid MAC scheme is required to differentiate the channel access between delay-sensitive applications and high data rate applications, where time slots are allocated to delay-sensitive traffic and data nodes occupy portions of channel time via contention to exploit traffic multiplexing gain (Zhang et al. 2010, 2011). With a varying heterogeneous network traffic load, how to adaptively allocate time slots to delay-sensitive applications and adjust the channel access parameters among data devices to achieve consistently bounded packet loss rate and maximum data throughput needs investigation.

Adaptive MAC Solutions

As stated precedingly, adaptive and hybrid MAC solutions are desired to coordinate packet transmissions among devices in an IoT-based MANET for achieving consistently maximum network performance, by adapting to a varying number of end devices and providing differentiated QoS guarantee. In the following, the technical steps to develop adaptive MAC solutions are presented for a homogeneous service scenario (i.e., support only high-rate data service) and for a heterogeneous service scenario (i.e., support both voice and data applications), respectively.

Homogeneous Service Scenario

Consider a fully connected MANET (i.e., each device is within the one-hop transmission range of any other device.) with a single and error-free wireless channel. Note that developing an adaptive MAC solution for a multi-hop MANET is considered in one of our recent works Ye and Zhuang (2017a). There is no central controller in the network, and devices coordinate their packet transmissions in a distributed manner.

Packet transmission failures are due to channel contention collisions. All devices in the network are assumed homogeneous, generating the same type of high-rate data application. Each device randomly chooses its destination among other devices and can send packets to and receive packets from other devices in the half-duplex mode. Every device has a unique device identifier (ID) that is randomly selected and included in its transmitted packet headers. Devices are synchronized in time by receiving an 1PPS signal periodically with a global positioning system (GPS) receiver. The total number of devices in the network is denoted by N , which varies slowly when devices move in or move out the network coverage area. Traffic arrivals at each device are assumed to follow a Poisson process with the rate parameter λ packet/s.

To establish an adaptive MAC framework in the presence of a varying number of devices, a hybrid MAC solution (Ye et al. 2016) is proposed to switch MAC frame structures between the CSMA/CA-based IEEE 802.11 DCF and a dynamic TDMA (DTDMA) scheme (Wilson et al. 1993) under different network load conditions. The DCF with exponential backoff for collision resolution achieves high data throughput when the number of devices is low, but experiences low channel utilization as the transmission collisions are accumulated in high network load conditions. For the DTDMA, time is divided into a sequence of frames, as shown in Fig. 1. Each frame consists of a control period and a data transmission period. The control period has a number of constant-duration minislots used for local information exchange to allocate time slots in the data transmission period to each device. The time slot allocation is conducted in a distributed way to fit the MANET

scenario. The number of minislots indicates the maximum number of end devices that can be admitted in the network. The data transmission period is composed of a number of data slots, which equals the current device number in the network, and the duration of each data slot is set the same as one data packet length. We assume that all data packets have an identical and fixed packet length. Since the DTDMA eliminates packet transmission collisions, its performance is superior to the DCF in a high network load condition. Therefore, with the consideration of these two candidate MAC schemes, the proposed adaptive MAC solution uses a separate mediating MAC entity (Doerr et al. 2005) working on top of the MAC candidates maintained at each device to make MAC switching decisions according to the variation of the number of devices, N , in the network.

To maintain consistently maximum network throughput by switching between the MAC candidates, the optimal MAC switching threshold (i.e., the optimal number of devices N^*) needs to be determined. To this end, a unified and closed-form performance analytical framework (Ye et al. 2016) is established for the aggregate network throughput with respect to the number of devices N for both DCF and DTDMA schemes, based on *least-squares curve fitting* and *M/G/1 queueing analysis*. For the throughput analysis, both traffic non-saturation (i.e., the transmission buffer of each device can be empty) and traffic saturation (i.e., each device always has packets to be transmitted) conditions are considered. For a traffic non-saturation condition, closed-form throughput analytical expressions $H_1(N, \lambda)$ and $H_2(N, \lambda)$ are established in a function of N and λ for the DCF and the DTDMA, respectively. With the increase of N , packet service rate for each

Adaptive Medium Access Control for Internet-of-Things-Enabled MANETs, Fig. 1 A DTDMA frame structure

device decreases, making the network operating in DCF or DTDMA enter the traffic saturation state. Thus, the throughput for the DCF and the DTDMA is also analyzed in a closed-form function of N , denoted by $H_3(N)$ and $H_4(N)$.

To calculate the optimal MAC switching threshold, denoted by N^* , throughput comparison between the two MAC candidates is conducted based on the developed closed-form performance analytical models. Since DCF and DTDMA have different network load points to enter the traffic saturation state, the following four combinations of traffic load states for both MAC schemes should be taken into consideration for the performance comparison: (1) the network is in the traffic saturation state for both MAC schemes; (2) the network is in a traffic non-saturation state for both MAC schemes; (3) the network is saturated for the DCF and non-saturated for the DTDMA; and (4) the network is saturated for the DTDMA and non-saturated for the DCF. Then, the optimal MAC switching threshold in terms of the number of devices, N^* , in the network can be determined, which also varies with the traffic arrival statistics λ at each device. Therefore, the adaptive MAC solution consistently makes the MAC switching decision at an optimal point (i.e., the DCF is operated when $N < N^*$ and is switched to the DTDMA when $N \geq N^*$) to achieve maximum aggregate network throughput.

Heterogeneous Service Scenario

To support heterogeneous service types, an adaptive and QoS-aware MAC solution is required. Consider the same system model as in the homogeneous service scenario except that both delay-sensitive voice devices and high-rate data devices are present in the network. The number of voice and data devices are denoted by N_v and N_d , which are slowly varying with time. For the delay-sensitive voice service, packet arrivals at each voice device follow an *on/off* model (Wang et al. 2007), which is a two-state Markov process with the *on* and *off* states being the traffic generation and traffic suppression phases, respectively. The durations each device stays in *on* and *off* states are independent and exponentially

distributed with respective average of $\frac{1}{\gamma}$ and $\frac{1}{\delta}$. During the *on* state, packets arrive periodically with the constant rate α packet/s. Each voice packet has a hard delay bound requirement, so that packets received beyond the delay bound are dropped. Therefore, the voice service has a packet loss rate bound requirement denoted by P_l . For the data service, each device is expected to access the channel by exploiting resource multiplexing gain to achieve as high as possible data throughput. All data devices are assumed in the traffic saturation state.

To satisfy the QoS requirements from both voice and data services, a QoS-aware hybrid MAC scheme is proposed to differentiate the channel access among voice and data devices (Ye and Zhuang 2017b), where voice devices are allocated time slots in a distributed way to guarantee a bounded packet delay by avoiding contention collisions and data devices contend for the channel access according to a truncated CSMA/CA (T-CSMA/CA) scheme to exploit high resource multiplexing gain. Time is partitioned into a sequence of fixed-duration superframes, as shown in Fig. 2. The duration of each superframe, denoted by T_{sf} , is set the same as the packet delay bound for voice traffic. Each superframe is composed of a control period, a TDMA period, and a T-CSMA/CA period, the durations of which are denoted by T_c , T_d , and T_s . The control period consists of a number N_{mi} of constant-duration minislots, each with an exclusive minislot sequence number (MN). Each voice device selects a unique minislot to broadcast and exchange its local information among its one-hop neighbors for distributed data time slot scheduling in the following TDMA period. Thus, N_{mi} also indicates the maximum number of voice devices (i.e., voice capacity) that can be admitted in the network. The TDMA period is divided into multiple equal-duration data transmission slots, each of which has a unique data slot sequence number (DN). Every active voice node (i.e., having non-empty transmission buffer) occupies one data slot to send a number of packets (a voice burst) generated during the previous superframe time. The number of

Adaptive Medium Access Control for Internet-of-Things-Enabled MANETs, Fig. 2 A hybrid MAC superframe structure

voice bursts scheduled in each TDMA period is indicated by N_{sv} . To provide voice traffic guaranteed service quality, a maximum fraction ρ (< 1) of channel time in each superframe is allocated to voice traffic, including the control period and the TDMA period. The voice capacity N_{mi} can be determined based on ρ and the packet loss rate bound P_l . In the T-CSMA period, data devices contend the channel according to the CSMA/CA with exponential backoff with periodic interruption of the control period and the TDMA period in each superframe.

Next, a traffic-adaptive time slot allocation mechanism is presented according to instantaneous voice traffic load in the network. Each voice device randomly selects a minislot from the control period of a superframe after the time synchronization and broadcasts a control packet in the selected minislot to its one-hop neighbors. A control packet sent from a tagged device contains the following important information: (1) device IDs from its one-hop neighbors including the tagged device; (2) MN of the minislot occupied by the tagged device; (3) buffer occupancy bit (BO), $BO = 1$ if the device's transmission buffer is non-empty and 0 otherwise; and (4) previous DN, indicating the DN of the occupied data slot from the tagged device in previous superframe, with $DN = 0$ if the device was not allocated a data slot in the previous superframe. The selection of one minislot from the tagged device is considered successful if the broadcast control packets at subsequent minislots following the selected minislot contain the tagged device ID, and thus the same minislot will be selected in every subsequent superframe. Otherwise, collision happens for accessing the minislot, and all the devices involved will wait until the next superframe for

a new minislot selection. With the consideration of the *on/off* traffic statistics, only active voice devices (i.e., the devices with $BO = 1$ in broadcast control packets) are allocated data transmission time slots after accessing the minislots, to adapt to instantaneous voice traffic load. Two categories of active voice devices are defined: category I and category II. A category I device is currently active but was not allocated a data slot in previous superframe, whereas a category II device is active in both current and previous superframes. Since the activation of category I device is at some random time instant before its minislot accessing time at current superframe, category I devices are prioritized over category II devices for the time slot scheduling. Specifically, category I devices are scheduled data time slots first by following their minislot accessing sequence to minimize the packet delay bound violation probability, under the condition that each category II device can be scheduled a time slot no later than the same time slot as in previous superframe.

After the TDMA period, the data devices contend for the channel access by employing the T-CSMA/CA scheme. The T-CSMA/CA is similar as the CSMA/CA with exponential backoff, except that the contention-based packet transmissions in one superframe are periodically interrupted by the presence of its subsequent superframe. Therefore, the performance of T-CSMA/CA is different from the CSMA/CA in the following two aspects: (1) the packet waiting time before transmission is enlarged by the control period and the TDMA period of each superframe; and (2) before transmitting one packet at the end of the exponential backoff phase, each device needs to check whether the remaining time in current superframe is

Adaptive Medium Access Control for Internet-of-Things-Enabled MANETs, Fig. 3 An illustration of T-CSMA/CA period in each superframe

enough to transmit at least one packet. If the remaining time is less than the summation of a complete packet transmission time (T_{pk}) and a guard time (T_{gt}), a virtual conflict occurs and $(T_{pk} + T_{gt})$ is the duration of the conflict period, as shown in Fig. 3. Then, all devices involved in a virtual conflict are required to hold on the packet transmissions until the beginning of subsequent T-CSMA/CA period.

The optimal parameters of the proposed hybrid MAC solution are derived, which are adaptive to varying numbers of voice and data devices to achieve bounded voice packet delay and consistently maximum data throughput. For the delay-sensitive voice service, given the maximum fraction of channel time, ρ , allocated to voice traffic in each superframe, the voice capacity N_{mi} supported in the network is analyzed, which is also the number of minislots configured for the control period of each superframe, to guarantee the voice packet loss rate bounded by P_l . Given N_v , the maximum number of voice bursts (data slots), denoted by N_{sm} , that can be scheduled in each superframe to achieve P_l is then determined. Since the actual number of scheduled data slots in each superframe is likely less than N_{sm} , the average number of scheduled data slots $\overline{N_{sv}}$ and the average duration $\overline{T_d}$ of each TDMA period are also calculated. Moreover, N_{sm} , $\overline{N_{sv}}$, and $\overline{T_d}$ are dynamically adapted to the variation of N_v to achieve a consistently bounded voice packet loss rate. After obtaining T_c and $\overline{T_d}$, the average duration $\overline{T_s}$ of the T-CSMA/CA period is also determined, which is employed for channel access by N_d data devices.

Therefore, the aggregate data throughput S_d in the T-CSMA/CA period of each superframe is further derived in terms of N_v , N_d , and the packet transmission probability τ_d from each device at a backoff slot. After some algebraic manipulation and certain approximation, the optimal transmission probability τ_d^{opt} and the corresponding optimal contention window size CW^{opt} to achieve maximum aggregate data throughput S_d^{max} are obtained in closed-form expressions of N_v and N_d . With the derived performance analytical models, the optimal MAC parameters CW^{opt} and τ_d^{opt} can also be dynamically adjusted with variations of N_v and N_d . Therefore, the proposed hybrid MAC solution in supporting heterogeneous services optimizes the MAC configurations and adapts the optimal MAC parameters to heterogeneous traffic load conditions for maintaining consistently maximum network performance.

Our proposed adaptive MAC solutions for both homogeneous and heterogeneous service scenarios are useful in an IoT-based network environment, where conventional cellular communication infrastructures are inaccessible and devices are interacted via an ad hoc networking. For example, in a postdisaster area, a large number of smartphones and smart sensors are required to be interconnected for information dissemination. The proposed MAC solutions are efficient in coordinating channel access from the smart devices in an infrastructure-less manner and adapting the MAC performance to the network load fluctuations due to device activation/deactivation and device mobility.

Numerical Results

Simulation results are provided to verify the effectiveness of the proposed adaptive MAC solutions. All simulations are carried out by using the network simulator OMNeT++. In the simulation, devices are randomly scattered over a 100×100 m square region and are within one-hop communication ranges of other devices. Each source device randomly selects its destination among the other devices. For the homogeneous service scenario, devices are with the same type of high-rate data application. Packet arrivals at each data device are assumed to follow a Poisson process with the average packet arrival rate set as 300 packet/s for the traffic saturation state (results for a traffic non-saturation state are provided in Ye et al. 2016). For the heterogeneous service scenario, there are a mixture of delay-sensitive voice devices and high-rate data devices in the network. Voice traffic is generated periodically during the *on* state with the rate of 50 packet/s. Other system parameters for the simulation are provided in Ye et al. (2016) and Ye and Zhuang (2017b).

Performance comparison between DCF and DTDMA is conducted for the homogeneous service scenario. Figure 4 shows the aggregate saturation throughput for both candidate MAC protocols with the variation of N . It can be seen that the optimal MAC switching threshold, N^* , exists at the network load point when the two MAC candidates achieve the same throughput. Based on the derived closed-form performance analytical models, the optimal MAC switching threshold can be determined in a distributed way with low complexity, upon which the adaptive MAC solution achieves consistently maximum network throughput.

For the proposed QoS-aware hybrid MAC solution, the voice packet loss rate is evaluated in Fig. 5. It is verified through simulations that the proposed distributed and adaptive time slot allocation mechanism always guarantees a packet loss rate below the analytical bound as long as the number of admitted voice devices is within the voice capacity. Although the busy tone-based MAC scheme (Wang et al. 2007) achieves a bounded packet delay in a low network load con-

dition, the transmission collisions among voice devices are accumulated as the network load increases, leading to degraded service perfor-

mance. The average T-CSMA/CA channel utilization within each hybrid MAC superframe is shown in Fig. 6, which is defined as the ratio of

average time for successful data transmissions inside a T-CSMA/CA period over the length of the T-CSMA/CA period. Since MAC parameters are optimized for the T-CSMA/CA, the channel utilization is consistently maximum with respect to a varying N_d .

Conclusion

In this entry, the backgrounds of distributed and adaptive MAC schemes for an IoT-enabled MANET are investigated. Novel adaptive MAC solutions are presented for both homogeneous and heterogeneous service scenarios. For the homogeneous service scenario, a hybrid MAC scheme is proposed to switch between the IEEE 802.11 DCF and the DTDMA according to the network load conditions. Based on the throughput analysis of both MAC candidates, an optimal MAC switching threshold is derived in terms of the number of devices in the network. For the heterogeneous service scenario, a QoS-aware hybrid MAC scheme is presented to differentiate the channel access for voice and data devices, where adaptive time slot allocation is conducted for voice traffic and a T-CSMA/CA scheme is employed for data traffic. The MAC parameters of the proposed scheme are optimized and are adaptive to the heterogeneous network traffic load, to achieve bound voice packet delay and consistently maximum aggregate data throughput. Simulation results are presented to verify the advantages of the proposed schemes. The applications of the adaptive MAC solutions are also discussed.

Definitions

Distribution system monitoring refers to key technologies for monitoring wide-area power distribution systems, between the substation and customer meters, to facilitate distribution grid planning and operation.

Background

Power distribution systems had a simple design historically. With radial topology, one-way power flow, and predictable demand curves, distribution system planners and operators were only required to evaluate the envelope of design conditions, such as peak loads and fault currents, to ensure reliability and power quality. Thus, there has been little need for costly telemetry beyond the substation, which was remotely monitored through supervisory control and data acquisition (SCADA) at several-second intervals. SCADA is a technology that has been in place for decades to connect sensing and control nodes, mostly in the transmission system, to a control room (Northcote-Green and Wilson 2006) using dedicated telephone lines, cellular, radio, or power line communications.

In recent years, the rapid growth in the deployment of controlled loads and distributed energy resources (DER) has led to unprecedented amounts of variability and uncertainty, which complicate distribution system planning and operation. This has necessitated more comprehensive monitoring of distribution circuits, and a novel planning and operation paradigm centered around pervasive monitoring, real-time analytics, and closed-loop control (Ardakanian et al. 2016).

Foundations

In light of new and complex grid dynamics that span multiple timescales, the operators must closely monitor the voltage and current

waveforms at different locations to detect and characterize certain behaviors, such as harmonics and oscillations, which could not be observed by the traditional SCADA system. This calls for an advanced distribution system monitoring solution which

- has low cost and complexity of deployment,
- covers both primary and secondary distribution networks,
- provides high-resolution measurements at multiple locations,
- uses precise time synchronization so that measurements can be compared across locations,
- utilizes a communication network that provides
 - stable and high bandwidth to allow for transferring high-sample-rate measurements from thousands of end nodes to upstream aggregation nodes and decentralized controllers,
 - low latency which is necessary for real-time applications, such as situational awareness, fault detection, and automated demand response,
 - high degree of reliability, or, equivalently, low link outage and packet loss probabilities,
- incorporates mechanisms to prevent unauthorized access, data manipulation, and denial of access to the sensing and control nodes,
- leverages an extensible data processing pipeline, high-throughput data stores, and real-time event triggers to provide a deeper insight into the operating state of the grid.

Two technologies have emerged in the last couple of years, namely, *smart meters* and *distribution-level phasor measurement units* (D-PMUs), which together can constitute the data acquisition layer of a well-suited distribution system monitoring system that meets the above requirements.

These technologies differ mainly in physical quantities they can measure, the time granularity of data, the location of sensors, and communication requirements. Smart meters are deployed at customer premises, recording their energy usage

and voltage level hourly or more frequently (up to every 15 min). The meters send the recorded data at regular intervals to the utility's data center using wireless or wired communications (Gungor et al. 2011). The smart meters, communications networks, and the utility's data management systems are collectively known as *advanced metering infrastructure* (AMI).

The D-PMUs (NASPI Distribution Task Team 2018) offer higher precision and resolution than smart meters. They sample voltage and current waveforms at a high frequency (usually at 120 Hz) and assign a precise time stamp to the measured quantities. The measured quantities are typically voltage and current *phasors* along with frequency, where a phasor represents the magnitude and phase angle of voltage or current. The D-PMUs are installed on distribution circuits supplementing the existing SCADA system by monitoring the network downstream of the substation. The data streams produced by a network of D-PMUs, termed *phasor network*, are aggregated by a small number of phasor data concentrators (PDCs), enabling fast comparison of time-synchronized phasor measurements from multiple locations before they reach the utility's data center. Given the bandwidth requirement of a phasor network, a broadband cellular network technology, such as 4G, is typically used for sending phasor measurements to the utility.

The smart meters and D-PMUs complement each other in the sense that they respectively monitor the end nodes and intermediate nodes in the distribution network. Moreover, in some applications, the availability of smart meter data can compensate for the lack of higher-resolution phasor measurements at some upstream nodes.

Implications for the Grid Planning and Operation

Distribution system operators can utilize the fine-grained measurements along with appropriate analytical tools for many important applications that concern planning and operation of the

Advances in Distribution System Monitoring, Table 1 Applications of distribution-level phasor measurement units

Application	Data streams	Analysis	Minimum resolution
Topology detection	Voltage phasors	On-line	1 cycle
Phase identification	Voltage phase angle	Off-line	1 s
Model parameter estimation	Voltage and current phasors	Off-line	1 s
State estimation	Voltage and current phasors	On-line	1 s
DG characterization	Voltage and current phasors	Off-line	1 min
Event detection/localization	Voltage and current phasors	On-line	1 cycle
Equipment health monitoring	Voltage and current phasors	Off-line	1 min
Outage management	Voltage and current magnitudes	On-line	1–15 min
Phasor-based control	Voltage phasors	On-line	1 cycle

distribution system (Meier et al. 2017). These applications are outlined below:

- *Topology detection* is to determine the set of energized lines and the status of switches to understand the real-time operational structure of the distribution network.
- *Phase identification* is to identify and track the connectivity and loading of the three AC phases throughout the network.
- *Model parameter estimation* is to compute impedances of distribution components, such as line segments and transformers, and update the distribution system model.
- *State estimation* (Abur and Expósito 2004) is to determine unknown state variables, for example, voltage magnitudes and phase angles at specific buses, given a set of known or measured state variables.
- *Distributed Generation (DG) characterization* is to separate the net-metered distributed generation from load.
- *Event detection and localization* is to detect and classify short-term operational and power quality events and pinpoint them to a small part of the distribution network.
- *Equipment health monitoring* is to detect and monitor equipment health issues or early signs of equipment aging to prevent damage to the equipment and support system upgrade decisions.
- *Outage management* is to automatically and reliably detect outages to reduce their duration and the system restoration cost.

- *Phasor-based control* is to incorporate phasor measurements in the feedback control of distribution system components and active end nodes, e.g., solar inverters, battery storage systems, and electric vehicle chargers.

Table 1 describes which physical quantities must be measured and what time granularity is sufficient for each of these applications.

Analog and Digital Communications

Xin-Lin Huang
Tongji University, Shanghai, China

Synonyms

Analog and digital communications

Definitions

The analog signal can be one of infinite number of values, while the digital signal can only be one of finite number of values. The analog signal transmission from one part to other parts is called analog communications, while the digital signal transmission from one part to other parts is called digital communications.

Historical Background

In practice, most signals that exist in the nature are analog signals, such as voice, image, video, temperature, pressure, and so on. There are

infinite numbers of possible values for analog signal, which is continuous with time in most cases. According to the Nyquist theorem, the low-pass and band-pass analog signals can be converted into digital signals through sampling, quantization, and coding processes, which is known as analog-to-digital converting (ADC). During the ADC process, the error called quantization error is caused in the quantization process. After ADC process, the analog signal is converted into digital signal as “0” and “1” binary sequence (Hui and Yeung 2003).

The modulation modes adopted in analog communications include amplitude modulation, frequency modulation, and phase modulation. Digital communication system uses digital amplitude modulation, digital phase modulation, digital frequency modulation, and APK modulation. Since the digital signal can only be one of finite number of values, the main difference of demodulations between analog and digital communications is that a sampling and decision module is used in digital communications. The sampling and decision module maps the demodulated signals into one of the finite number of values. If the noise caused in the digital communication systems is less than the noise tolerance threshold, it can be removed by the sampling and decision unit. However, the quantization noise is irreversible in digital communications.

Analog and digital communications are adopted in mobile communications. The emergence of mobile communications began in the early twentieth century. The mobile communication schemes have experienced from analog communications to digital communications. In 1G to 4G communications, 1G cellular network adopts analog communications, and the others are digital communications (Kumar et al. 2010).

Foundations

Analog Communication Systems

The analog communication systems transmit analog signals, which have infinite number of possible values. Therefore, the receiver cannot com-

Analog and Digital Communications, Fig. 1
Analog communication systems model

Analog and Digital Communications, Fig. 2 Digital communication systems model

pletely eliminate the interference noise caused by the transmission channel.

Due to the amplitude distortion and phase distortion in communication systems, the performance of analog communications is affected. It means that the analog signals sent by the transmitter will not be received by the receiver accurately. The analog communications can be classified into amplitude modulation, phase modulation, and frequency modulation according to which parameter of the carrier is modulated by the transmitting analog signals. The diagram of the general analog communication systems is shown in Fig. 1. The performance of analog communication systems is merited by the signal-to-noise ratio of the reconstructed signals at the receiver.

Digital Communication Systems

The digital communication systems transmit the digital signal which can only be one of finite number of values. The sampling and decision module at the receiver can completely elimi-

nate the interference signal if it is smaller than the noise tolerance threshold and thus greatly improving the quality of digital communications and facilitating long-distance transmission with relays. The general digital communication system is shown in Fig. 2. The performance of digital communication systems is merited by the symbol error probability of the decoded digital sequence at the receiver.

Different from Fig. 1, the source coding and channel coding are adopted at the transmitter, and the corresponding source decoding and channel decoding are adopted at the receiver. Due to the overwhelming bias toward digital communications, there is no effective analog channel coding designed for analog communications.

Discussions

In digital communications, the irreversible quantization error caused by ADC process is introduced into digital transmission. The source coding leads to a serious dependence among the transmission stream and has the drawback of

error propagation during decoding. In the transmission process on time-varying fading channel, the channel quality changes dynamically. When the channel quality is higher, the digital modulation cannot obtain extra transmission quality after correctly demodulating the digital signal.

In analog communications, due to lack of effective analog channel coding scheme, the analog communications are not good at overcoming channel noise. However, analog communications can be well adapted to the dynamics of channel quality, and better signal-to-noise ratio can be obtained when the channel quality is higher. Hence, effective analog channel coding and power allocation schemes are encouraged in future research works.

Key Applications

The analog communications are mainly adopted in telephone communications, radiobroadcasting and television services, and so on. Currently, digital communications are widely used, such as computer communications, mobile communications, and digital television (Hui and Yeung 2003; Tachikawa 2003).

Definitions

Anomaly detection for Internet of Things (IoT) system is to automatically detect whether the IoT devices, components, or systems operate normally or not. Usually there are multiple sensors or external monitors that observe the signals sent from the operating IoT systems. The detection module analyzes the signals to determine whether the system's behavior is normal or abnormal.

Historical Background

The IoT systems link the heterogeneous sensors and IoT servers to provide the IoT applications such as healthcare, industrial automation, environment monitoring, and so on. Because the decade aged IoT systems and new IoT systems may coexist, it is not easy to implement the monitors into the integrated IoT systems. It is usually to treat the integrated IoT system as a black box. Furthermore, because the signals come from one or more types of sensors (i.e., heterogeneous sensors), it is complicated for the monitors to analyze the signals from the IoT systems. One of the solutions to resolve the issue is to use the rules defined by the expert, but it usually takes time and cost. The data-driven technologies can

be applied for anomaly detection in IoT systems. Some of the previous works using these data-driven technologies are summarized as follows:

The works (Xie et al. 2017; Juvonen et al. 2015) built the statistical model based on the normal data. If a data sample does not follow the statistical model, it is judged as an abnormal data point. The work (Zhang et al. 2016) used supervised machine learning algorithms to build a classification model to check whether a data sample is normal or abnormal. It is required to label each data sample as “normal” or “abnormal” in supervised learning algorithms. The works (Valenzuela et al. 2013; Shin et al. 2011) used unsupervised machine learning algorithms to build clustering models. Because it does not rely on the labeled data, it can save lots of labeling effort.

Foundations

Anomaly detection techniques can be applied in many domains such as intrusion detection, system health monitoring, anomalous event detection in sensor networks, and so on. The anomalies could be caused by external factors (e.g., network attacking and human mistake) or internal factors (e.g., hardware failure and resource exhaustion). The anomaly detection techniques can be grouped into the following categories: density-based (Breunig et al. 2000), statistical-based (Xie et al. 2017; Juvonen et al. 2015), clustering-based (Zong et al. 2018), and the machine learning-based (Zhang et al. 2016) techniques. These techniques use historical data to build up models to determine whether the data sample is normal or abnormal. In most cases, the anomalies are rare events (i.e., less data points for the anomalies). It is very hard to directly learn the anomalous patterns from less data samples. To resolve the issue, we may only use the data samples of normal events to build up the model for anomaly detection. If a sample data does not follow the model (e.g., does not fall into the distribution of the data points of normal event), it is determined as an abnormal event.

Key Applications

In the following, we elaborate on some IoT applications (Porkodi and Bhuvaneswari 2014) for which anomaly detection can be applied:

Industrial Environment/System

In Industry 4.0 (Stojanovic et al. 2016) for automation and data exchange in the manufacturing industry, wireless sensor networks are deployed to monitor the physical environment to ensure that the manufacturing systems operate continuously and safely. With the help of the monitoring sensors, the status of the monitored object is represented by several metrics, with which the anomaly detection can determine whether the status of the monitored object is normal or abnormal.

Smart Home

In the smart home application (Fahad and Rajarajan 2015), the electrical devices, such as air-condition, television, and so on, are connected with the IoT network, through which users can interact with the devices. The anomaly detection for smart home can be applied for home security, where it can detect whether someone without authority breaks into, or check whether the door is locked or not.

Health Monitoring

With the wearable devices connected to the IoT network, the human's physiological status can be monitored remotely in real time, which makes elderly care (Shin et al. 2011) or healthcare more functional. The anomaly detection can be applied for checking whether the status deviates from distribution of the historical data, and determines whether the owner of the devices is in trouble (i.e., an emergency event occurs). It can also reduce the response time for an emergency event. Applying anomaly detection helps health monitoring system be able to react more quickly.

Connected Cars

A connected car is a vehicle with capability to connect to other vehicles, devices, and networks through wireless local area networks which assists users to drive (Kwak et al. 2016). One of the applications of the anomaly detection on the connected car is to check the user's driving behavior (e.g., it can determine whether the user has dangerous driving behavior), or check if the functionality of the car is in good status.

Smart City

In the smart city (Difallah et al. 2013), the sensors and activators (e.g., traffic light) are connected to IoT network. Examples of the smart city applications include traffic flow management and environmental monitoring. The anomaly detection in smart city can be applied to detect the car accident (i.e., abnormal traffic flow).

IoT Network Security

In the IoT network security (Hodo et al. 2016), the traditional firewall determines whether a packet can go into the Intranet by referencing the predefined security rules. However, it is hard to identify new types of attacks by using the predefined rules. The unsupervised anomaly detection mechanism can train a behavior model by using the normal Internet traffic. The model can be used to determine abnormal network traffics, e.g., attack patterns, and it can reduce the effort for human expert to find out the attack patterns.

Definition

A Wireless Sensor Network (WSN) consists of spatially distributed autonomous devices using sensors to monitor physical or environmental conditions. A WSN system incorporates a gateway that provides wireless connectivity back to the wired world and distributed nodes. Machine learning (ML) is the science of getting computers to learn and act like humans do and improve their learning over time in autonomous fashion, by feeding those data and information in the form of observations and real-world interactions.

Introduction

Wireless Sensor Networks (WSN) is a vital component in Internet of Things (IoT). The small sized, low powered sensors are capable of monitoring and collecting data from environment. Most of the recent research works have not concentrated to provide a solution for analyzing the potentially huge amount of data generated by these sensor nodes. Thus, there is a need for machine learning (ML) algorithms in WSNs. When volume, velocity, and variety of data generated by WSN is very high, then data analytics tools are needed for data aggregation and clustering. ML tools are used in several applications such as intrusion detection, target tracking, healthcare, home automation, smart city. The main aim of this entry is to provide a basic knowledge in machine learning and its applications in WSN.

Background

Generally, the designers of sensor network symbolize machine learning as a branch of artificial intelligence and it is a collection of algorithms that is capable of creating prediction models. On the other hand, ML experts characterize it as a field, which is having huge amount of patterns and themes useful in sensor network applications (Alsheikh et al. 2014).

Supervised Learning

Supervised learning is merely a formulation of the concept of learning from examples. Supervised learning approach is used to resolve various issues for WSNs such as event detection, objects targeting, localization (Shareef et al. 2008), processing of query, Medium Access Control (MAC), intrusion detection, security, data integrity, and QoS.

Unsupervised Learning

No output vectors or labels are provided in unsupervised learning. Data sets are classified by finding the similarities among them. Unsupervised learning algorithm determines the concealed rela-

tionships and it can be used for solving the problems in WSN, where relationship between the variable is complex. These types of algorithms are mainly used for clustering and collection of data in WSN.

Reinforcement Learning (RL)

It allows the agent to learn from the environment by interacting with it. Here, sensor nodes learn to capture the best measurement in order to maximize the advantage. The most famous reinforcement learning algorithm is Q-learning, in which every node tries to extract measurements which are expected to increase the rewards. Sensor nodes regularly update the bonuses it has achieved derived from the actions taken at a given state. Total rewards of future can be computed by the equation:

$$\begin{aligned} Q(s_t + 1, \alpha_t + 1) \\ = Q(s_t, \alpha_t) + \gamma (r(s_t, \alpha_t) - Q(s_t, \alpha_t)) \end{aligned} \quad (1)$$

(.) indicates the incentive for taking the action a_t at state s_t and γ is the rate of learning, which decides how frequently the learning happens (between the values 0 and 1).

Machine Learning for Localization

A sensor node recognizes the position either by using GPS device or by any specific localization methods. One of such method is to collect the knowledge (e.g., connectivity, pair-wise distance measure) on the subject of the whole network into single place, where the composed information is managed in a centralized manner and identify the nodes' locations using mathematical algorithms.

Security and localization are the two main applications of Support Vector Machine in WSN. The localization method (Tran and Nguyen 2008) for mobile node uses SVM and knowledge about connectivity capabilities. By using RSSI metric (Received signal strength indicator), it detects the node location. Despite the fact that Localized SVM is capable for distributed localization in a speedy manner, it is still susceptible to outliers in training data set.

A localization system based on Self-Organizing Map (SOM) (Paladina and Paone 2007) provides a few artificial intelligence (AI) features to sensor nodes. Without any supervision, SOM can able to learn how to classify. Self-Organizing Map is used on each sensor nodes in order to evaluate the position of the node. Eight anchor nodes spatial coordinates surrounding the unspecified node form the input layer. Output layer gives the special coordinates in 2D space of the unspecified node after the training. Demerit of this method is that nodes should be organized consistently throughout the monitoring area.

An improved localization using Support Vector Regression (SVR) (Wang et al. 2016) discusses about a novel extraction method of training data for localization model. It improves the accuracy of localization method without affecting the hardware cost. The location of the unknown node is found accurately using SVM-based learning with minimum number of anchor nodes (Mary Livinsa and Jayashri 2015). Accuracy is provided by finite size of grid cells. For larger scale networks, SVM-based DV-hop is suitable.

Machine Learning for Clustering and Data Aggregation

It is really difficult to transfer entire data to sink instantly in a large scale energy-constrained sensor network. An effective solution for this problem is to send the data to an aggregator node, which is also called as cluster node. The node aggregates information from all members of the cluster and sends to the sink or base station, thus reduces the energy consumption. Numerous algorithms are actually suggested for the election of Cluster Head to increase the energy efficiency. The machine learning dependent strategies can develop the advantages of clustering and aggregation of data between nodes in WSNs through several procedures.

- ML algorithm is used to identify and remove the nonfunctional nodes from routing schemes

and compress data at CH using dimensionality reduction method.

- Machine learning algorithms are executed for electing the Cluster Head efficiently, where election of suitable cluster head will considerably decrease the usage of energy and augment the network's lifespan.

The CH election problem can be solved by the application of Decision Tree algorithm (Ahmed et al. 2010) (DT). By considering prominent features as battery, distance, and mobility, DT is electing suitable cluster head. By estimating these features, DT can provide a proficient method for identifying link reliability in Wireless Sensor Networks. Role-Free Clustering (Forster and Murphy 2010) is a clustering method with Q-learning for WSNs. The ability of the cluster head is evaluated by Q-learning algorithm with active network parameters.

A distributed spectral clustering method to group sensor nodes on their location is proposed (Muniraju et al. 2017) to avoid data congestion. This is the combination of two algorithms, distributed eigen vector computation and distributed K-Means clustering. Eigen vector of graph Laplacian is calculated by distributed power iteration technique. Clustering on eigen vector is done by distributed K-Means algorithm. In order to establish the network topology, only the location information of sensor nodes is used and this information is not exchanged in the network. In (Park et al. 2013), energy efficiency is maximized by finding cluster head with k means algorithm.

The Self-Organizing Map (SOM) is unsupervised algorithm method that learns to map from high to low dimensional space. In Cluster-based self-Organizing Data Aggregation (CODA) architecture (Lee and Chung 2006), the nodes classify the aggregated data j^* as the winning neuron, which is having a weight $W(t)$ nearest to the value of input vector $X(t)$. With CODA scheme, quality of data is increased and energy consumption and network traffic are reduced.

Principal Component Analysis (PCA) algorithm is used for dimensionality reduction and famous in the field of data compression. Principle components are a set of orthogonal variables.

Main aim is to select the significant information from data concerning the principal components. Both data compression and dimensionality reduction are multivariate methods. This can reduce the amount of data transmission between the nodes in WSN. By selecting only the momentous principal components and tossing out the lower order components, it solves the big data problem into small data. For improving the process of data aggregation, the combination of following two significant algorithms is used along with Principal Component Analysis (PCA) in WSNs (Morell et al. 2016).

- Compressive Sensing (CS): The conventional scheme of "sample then compress" is recently replaced by CS. Compressive Sensing uses sparsity property of signal.
- Expectation-Maximization (EM): This algorithm comprises of two stages, an expectation stage and maximization stage. While performing its expectation (E) stage, EM evaluates the cost function by saving the current expectation of parameters. In the maximization (M) stage, it re-computes parameters that can minimize the estimation error.

Adaptive Learning Vector Quantization (ALVQ) is used to extract compressed model of information from the nodes accurately (Lin et al. 2009). ALVQ uses the LVQ learning algorithm with previous training data for predicting the code-book. This method reduces the needed bandwidth while transmitting data and improves the accuracy of correct reading restoration from the compressed information.

Machine Learning for Routing

Considering features such as memory and computational requirements, communication costs, wireless ad-hoc nature, restricted energy, mobility and topology changes, different ML algorithms are used for energy-efficient routing in WSNs.

In fuzzy logic-based routing method (Arabi 2010), the entire network is grouped into different clusters and the election of suitable cluster head

is based on fuzzy variables. The routing in WSNs depends on the combination of hybrid routing methods and fuzzy logic for improved energy savings and improved network life span. Energy and Delay Efficient Routing protocol for sensor network (EDEAR) (Sharma and Shukla 2012) is adaptive routing method (Kumar and Kumar 2010) using Reinforcement Learning (RL). It finds the best path with minimum energy consumption and end to end delay. RL renews routing tables and thus considers all the dynamic parameters that characterize the traffic. The adaptation of routing depends on the varying traffic conditions and hence minimizes data transfer time.

Energy-aware QoS Routing algorithm using Reinforcement Learning (EQR-RL) (Jafarzadeh and Moghaddam 2014) is able to balance QoS requirements and improve network life time. Using a random load balancing algorithm, next hop neighbor is chosen. QoS parameters such as number of hops, latency, and geographical distance are considered. Dynamics of the network is learned using Q-Learning technique and routing decision is made accordingly; however, the network state information is not maintained. Sensor Intelligence Routing (SIR) using Self-Organizing Map (Barbancho et al. 2008) detects optimal routing path. The combination of SOM and Dijkstra's algorithm model offers QoS guarantees like throughput, latency, duty cycle, and packet error rate.

Example Application Scenarios

Regression-Based Adaptive Incremental Algorithm for Health Abnormality Prediction (RBAIL)

This method employs a regression based incremental algorithm for providing the learning features (Srinivasan et al. 2013). The incremental learning system is wirelessly connected to the patient and receives the stream of input parameters from patient for a fixed time of interval. RBAIL algorithm performs regression on the important health parameters for predicting the

indiscretion of patient. System uses history of the patient to check whether previous anomalies were there in order to get the updates and feedbacks. Main features here are aggregation, learning, and prediction. Correctness of the parameter is verified during aggregation. If previous data and current input data are valid and parameter value is greater than a threshold value, then abnormality is detected. If the difference of current and predicted value becomes greater than a threshold, then doctor provides feedback to correct the learning algorithm.

Object Detection and Tracking in Wireless Sensor Networks

Prediction logic is used to predict the exact location of the sink node using current location (Vaidehi et al. 2011). The estimated position is sent to Cluster Head to wake up the node which is in sleep mode. The combination of sleep wake scheduling, clustering, tracking, prediction logic, and shortest path routing minimize the energy consumption in sensor networks. Sink nodes awake cluster head that helps to reach target. Further complex events processing engine is used for detecting abnormal events in a multisensor scenario (Bhargavi and Vaidehi 2013; Gao et al. 2012).

Semantic Intrusion Detection System by Means of Pattern Matching and State Transition Analysis (SIDS)

Semantics Intrusion Detection System (SIDS) (Sri Ganesh et al. 2011) combines pattern matching, state transition, and data mining for increasing the accuracy of intrusion detection. Multiple sensors are deployed in the sensor area. The events generated by sensors are correlated in time spatial domain. The outputs from the sensors are symbolized as patterns and states. When the patterns generated by sensors violate the rule, it is detected as an intrusion. Semantics rules are developed using Another Tool for Language Recognition (ANTLR).

Online Incremental Learning Algorithm for Anomaly Detection and Prediction in Health Care

An Online Incremental Learning Algorithm (OILA) is proposed (Kirthana and Bhargavi 2014) for processing the data in online. It uses the combination of regression and feedback mechanism in order to decrease the prediction error and hence improves accuracy. The vital health parameters are received from the body sensors of a patient. Online Incremental Algorithm evaluates several parameters based on the received data and checks whether any anomalies are found. An alert is set to the doctor, if any anomalies are detected. Regression-based method is used to predict next instance. Prediction of each patient is personalized according to his/her health parameters. This algorithm calculates overall trend by *longvalue* and recent trend by *shortvalue* in health parameters. The parameters *maxthresh* and *minthresh* captures maximum and minimum threshold value of tolerance. Difference between *maxthresh* and *minthresh* is captured by a parameter *diffthresh*. Patient *sensitivity range* can be defined through sensitivity range parameter by the doctor. *History factor* is a parameter that defines number of times a patient affected to abnormalities. After reading every new instance, these parameters are updated, error is adjusted, and according to that prediction is made. The algorithm predicts the abnormality using updated parameters and triggers alert.

A Genetic Approach for Personalized Healthcare

Genetic Algorithm-based Personalized Healthcare System (GAPHS) (Vaidehi et al. 2015), uses a sensor integrated wearable chest strap for the non-invasive monitoring of physiological parameters and body parameters. Wrist wear wireless Blood Pressure (BP) sensor is used for monitoring blood pressure. A fingertip wearable oxygen saturation level (SPO2) sensor is used to detect blood oxygen saturation level. The abnormality levels of the vital parameters are classified into very low (VL), low (L), medium (M), high (H), and very high (VH) and encoded into a 5-bit

representation to determine the severity level of the patient. Using fitting function, the best chromosome that represents the personalized vital parameter of the patient is obtained. The proposed GAPHS provides an intelligent, personalized, and efficient healthcare system to serve the needy patient in right time by the doctor.

Dynamic Higher Level Learning Radial Basis Function for Healthcare Application

Traditional Radial Basis Function (RBF) has issues with using complete training set and large number of neurons. Due to these issues, computation time and complexity are increased. Dynamic Higher Level Learning RBF (DHLRBF) (Chandraskar et al. 2014) is applied to health parameters to find normal and abnormal category. The DHLRBF uses both cognitive and higher level learning component for effective classification with less complexity.

Sensor Based Decision Making Inference System for Remote Health Monitoring

Most of the existing methods have difficulty to differentiate between original and fall like patterns. Intelligent Modeling technique, Adaptive Neuro-Fuzzy Inference System (ANFIS) (Dhivya Poorani et al. 2012) is used for detecting the fall automatically with higher accuracy and less complexity. The data received from 3 axis accelerometer is categorized into five states (sit, stand, walk, lie, and fall) using ANFIS model. Mean, median, and standard deviation are selected for training the neural network. When the state is detected as fall, it examines ECG and heart rate of patient to check the abnormal condition and raise alarm.

Future Direction

The new revolution, Internet of Things is rapidly gathering momentum driven by advances in Sensor Networks and cloud technologies. The cloud has to provide security for sensed data. The storage for sensed data needs to be minimized by compression schemes. Multisensor data fusion is used for situation, object and threat refinement. The complex events sensed by sensor network

can be analyzed with data analytics tools to find the trends, patterns, and gain new insights and knowledge for variety of applications.

Social internet of things (SIoT)

Historical Background

Internet of Things (IoT) has been an integral component of our lives and thriving with new products and services. This term was first introduced by Kevin Ashton at Procter & Gamble (*P&G*) in 1999 (Ashton et al. 2009). He presented the idea that computers could be empowered to observe, identify, and understand the physical world with RFID (radio-frequency identification) and sensor technology. By now, this definition has evolved continually with the development of embedded systems, wireless sensor networks, machine learning, etc. As defined in ITU (2012), IoT is the network of interconnecting physical and virtual things which

have embedded information and communication technologies that allow these things to interact and exchange data. In addition to the personal devices such as smartphones, tablets, and laptops, IoT objects have been widely used in others fields which include, but not restricted to, agriculture (Mekala and Viswanathan 2017), smart city (Arasteh et al. 2016), education (Gul et al. 2017), manufacturing (Yang et al. 2018), medical and healthcare (Joyia et al. 2017), etc.

Existing technologies have enhanced the computing capacity of IoT objects, but most of them embedded in specific and necessary hardware features are only able to finish a particular task. In Guinard et al. (2010), the authors propose a platform that enables an individual to share the services offered by his smart objects with his friends or their objects through social networks of humans. Using interconnected objects to extend the Internet and consequently leading to efficient conversations is addressed in the study (Mendes 2011). In Atzori et al. (2011), the concept of *Social Internet of Things (SIoT)*, which is a social network among the objects of IoT, is formalized. Generally, a social network for human beings is a platform (like Facebook, Twitter, Instagram, etc.) which people and organizations can share user-generated content such as videos, photos, comments, posts, location, and so on. Members of this kind of platform prefer to interact and build social relationships via the Internet with those who share similar backgrounds, interests, or friends. For objects, the SIoT is a platform for global interconnected IoT objects to obtain social-like capabilities, which allow these objects to autonomously establish social relationships, request or provide services, and collaborate with others to achieve a common goal in an autonomous way with proper authorization from users.

As a new paradigm of IoT, SIoT introduces the social relationship concept among IoT objects. This does not mean that a common architectural model of social network services for human beings can be directly applied to SIoT. The differences between main components of social network platforms for humans (Boyd and Ellison 2007) and IoT objects are presented in Atzori

et al. (2011). And the explanations of main components of social network platforms for IoT objects are organized as follows:

- *ID management (ID)*: assigns a unique ID to each IoT object and manage existing objects.
- *Object profiling (OP)*: contains static and dynamic information about the object.
- *Owner control (OC)*: sets up rules to carry out access control, relationship control, and any other operations.
- *Relationship management (RM)*: is an important component based on the user-defined rules to establish, update, and terminate relationships among objects in a network.
- *Service discovery (SD)*: finds objects that can provide required services from the network, a very similar way to searching for friends and information from an online social network.
- *Service composition (SC)*: enables interaction between objects.
- *Trustworthiness management (TM)*: provides trust evaluation among objects for relationship management and information sharing.

In a SIoT network, several kinds of relationships can be defined among objects. The types and characteristics of social relations among IoT objects are systematically summarized in Atzori et al. (2012):

- *Parental object relationship (POR)*: established when objects are created in the same period by the same manufacturer.
- *Co-location object relationship (CLOR)*: established when objects are deployed in the same location.
- *Co-work object relationship (CWOR)*: established if the objects work on the same task.
- *Ownership object relationship (OOR)*: established when objects have the same owner.
- *Social object relationship (SOR)*: established when the owners get in touch and the objects are active.

These relationships among objects in SIoT should be established and managed *without human intervention*. Several SIoT architectures

based on the above components and relationships are introduced in the next section.

SIoT Architectures

A three-layered architecture model proposed in Zheng et al. (2011) for IoT should be introduced before the SIoT architectures, since several existing SIoT architectures are built upon this IoT architecture. In this architecture model, the sensor data are acquired by sensing devices in the *Sensing Layer*. Then these data are safely and reliably transmitted to the *Application Layer* through the *Network Layer*. The *Network Layer* is devoted to transferring data across different networks such as cellular networks, WLAN (wireless local area network), satellite communication networks, and so on. By applying distributed computing technologies to massive data, the *Application Layer* performs data processing and analysis intelligently to support intelligent control in the IoT.

The following are SIoT architectures summarized from existing research:

- An architecture consisting of the Server Side and Client Side is proposed in Atzori et al. (2011). This architecture has three layers on both sides. On the Client Side, the Objects Layer consists of different physical objects. The Object Abstraction Layer is used to harmonize communications among physical objects. The top layer on the Client Side consists of the Social Agent element and the Service Management element. The Social Agent element is designed for friendships and object profile updates, service discovery, and service request from the network. Management element provides interface for humans to control the object behaviors. On the Server Side, the Base Layer provides data storage and data management. The Component Layer includes the main components of SIoT (OP, DC SD, TM, ID, RM, and SC). Application Layer consists of interfaces to human, objects, and third-party services.

- A three-layer SIoT architecture is proposed in Atzori et al. (2012). This proposed system consists of three subsystems: the SIoT Server, the Gateway, and the Object. The SIoT Server has a Network Layer and an Application Layer. The Application Layer includes three sub-layers. The database of data storage, data management, and relevant descriptors is in the Base Sub-layer. The main components of the SIoT system discussed in the previous section are located in the Component Sub-layer; they provide main capabilities for the SIoT system. The Interface Sub-layer consists of the third-party interfaces for objects, humans, and services. The Gateway and the Object both have Sensing Layer, Network Layer, and Application Layer. The characteristics of devices decide the combination of these layers. But no matter what the combination is, the Application Layer includes SIoT Applications, the Social Agent, and the Service Management. The Social Agent communicates with the SIoT server to update its profile and friendship and also provides service discovery and service request. When it is necessary, it is devoted to direct communications between objects which are close to each other in the physical world as well. The Service Management Agent provides interfaces for humans to control the behaviors of the objects.
- An architecture with Actors, the Intelligent system, the Interface, and the Internet is introduced in Ortiz et al. (2014). The Internet is the foundation of this architecture; Actors in the architecture refer to humans and things who have equal rights to take part in managing data, executing queries, and receiving services and commands. The Intelligent system is devoted to coordinating the interactions between Actors; it also has capabilities of recommendation, data and context management, service discovery and search, and service and application management. The Interface provides ports for inputs and outputs of the interactions with the system.
- A distributed sensor storage for SIoT is presented in Wu et al. (2015). The Sensing Layer is responsible for collecting data from the physical world through sensors and other

objects. The Communication Layer transfers the sensing data collected from Sensing Layers to the users via the Internet, mobile network, etc. The Application Layer consists of consumer applications, enterprise applications, and government applications. Different services can provide data for different users. In this architecture, the IoT, consisting of the Internet and sensor network, can be organized into SIoT based on the social network. In SIoT scenarios, the sensors with large storage can help normal sensors which can only sense the environment to store the sensing data. The storage should be able to repair the lost fragment and to protect data secrecy.

- A four-layered SIoT architecture is introduced in Gulati and Kaur (2019). In this architecture, the Base Layer called Object Layer is where the IoT devices and sensors are deployed. Communication and collaboration among these objects are through local sensor networks. Communication technologies and protocols used by SIoT are defined in the Communication Layer. The SIoT Management Layer defines the SIoT platforms to manage SIoT services. The main components of SIoT that were introduced in the previous section are in this layer. The top layer is the Application Layer which provides APIs (application programming interfaces) for SIoT applications.

Key Applications

Following the theoretical development of SIoT, several projects have been proposed to integrate IoT objects into a social network. Existing SIoT platforms such as *Toyota Friend Network*, *Nike+*, *Xively*, and *Paraimpu* are summarized in Atzori et al. (2014). *Toyota Friend Network* is a private social network that allows Toyota customers to create a virtual community among them and interact with their own cars. For example, customers can get a maintenance alert from their cars and can connect to the dealerships to get service information through this social network. *Nike+* provides a platform for customers to share their fitness data in a social network. *Xively*

and Paraimpu are two similar platforms which enable objects to be connected to each other or to be linked to existing social networks so that these objects can respond to their owners' requests. Furthermore, Paraimpu allows users to share the data generated by objects with their friends. A protocol for traffic management in *social Internet of Vehicles (SIOV)* (an extension to the concept of SIOt) is presented in Jain et al. (2018). This protocol can improve the performance of data transmission over vehicular social networks. Other cases that use SIOt are illustrated in Afzal et al. (2019), for instance, smart shopping mart retailing, healthcare and telemedicine, traffic surveillance and road safety, and so on. In Fu et al. (2017), an intelligent painting device intended for children is designed based on SIOt. This device aims at creating a social network consisting of humans, objects, and emotion to facilitate the children's intellectual development and personality development.

Security and Trust in SIOt

As IoT devices are becoming more ubiquitous, IoT security has been a growing concern. Several IoT security incidents make people realize the importance of IoT security. In 2016, the largest DDoS attack was launched by an IoT botnet (Goodin 2016), a malware called *Mirai* that brought people's attention to the seriousness of IoT security. Beyond that, there are even more serious attacks related to daily life. For example, the vulnerable web camera at home can be used to pry into the owner's daily life by the attacker (Whittaker 2015). A Jeep over the Internet can be hijacked, and the attacker can gain access to many functions that could be used to cause a traffic accident (Rouse 2015). In 2017, the Food and Drug Administration (FDA) warned that cybersecurity vulnerabilities are identified in several medical devices (FDA 2017).

In order to address the security threats in IoT, a series of studies are carried out from different aspects including encryption, authentication, access control, network security, and application security (Zhou et al. 2018; Alaba et al. 2017;

Diro and Chilamkurti 2018; Jia et al. 2018; Liang et al. 2018; Zheng et al. 2018). In addition, object diversity and complex relationships among objects make security communication and trustworthiness management become more important and serious for SIOt (Nitti et al. 2014). Furthermore, related policies and laws should also be formulated to regulate the ethical use of SIOt (Berman and Cerf 2017).

Conclusion

As a new paradigm of the Internet of Things (IoT), the Social Internet of Things (SIOt) will create a brand-new way of communication and interaction for IoT objects. This article systematically introduces the definition and components of SIOt as well as the existing architectures and applications. Furthermore, security and trust issues which could bring great challenges to the development of SIOt are discussed at the end of this article.

Applications of Molecular Communication Systems

Tadashi Nakano, Yutaka Okaie, and Takahiro Hara
Osaka University, Suita, Japan

Synonyms

Molecular, biological, and multiscale communications; Nano-networks

Definitions

A molecular communication system is defined as a system of bio-nanomachines that transmit and receive information using chemical signals or molecules. A bio-nanomachine that constitutes a molecular communication system is made of biomaterials with or without non-biological materials, approximately 1–100 μm in size, and capable of processing molecules. Examples of molecular communication systems are naturally occurring biological systems such as bacterial populations, epithelial sheets, and immune systems where biological cells represent bio-nanomachines. Examples of molecular communication systems also include artificial or synthetic biological systems designed for specific applications such as biomolecular sensing and targeted drug delivery.

Historical Background

Molecular communication was proposed as an unexplored research area at the intersection of communications engineering and biology (Nakano 2017). The basic concept of molecular communication is simple (Fig. 1); sender and receiver bio-nanomachines communicate using chemical signals or molecules. To transmit information, sender bio-nanomachines generate “information molecules” that represent information (i.e., encoding in Fig. 1) and transmit the information molecules into the environment (sending). Information molecules propagate in the environment (propagation) and react to receiver bio-nanomachines (receiving and decoding). Namely, receiver bio-nanomachines receive information from information molecules.

Molecular communication research can be divided into its first phase (2005–2009) and second phase (2010–present). The first phase of research (2005–2009) focuses on experimentally recreating functionalities and components of naturally occurring biological systems. This includes the first prototype implementation of molecule transport systems using motor proteins

Applications of Molecular Communication Systems, Fig. 1 Molecular communication (Nakano 2017)

and DNA molecules (Hiyama et al. 2008a). This also includes experimental demonstration of signal amplification mechanisms through calcium signaling (Nakano et al. 2009), self-organized microtubule networks (Enomoto et al. 2006), and encapsulation of information molecules and transport of information molecules from liposomes to biological cells (Moritani et al. 2010).

The second phase of molecular communication research (2010–present) has seen a wider variety of research topics concerning molecular communication. This phase of research includes the use of communication theory and mathematical tools to understand physical properties of molecular communication (Mahfuz et al. 2010; Farsad et al. 2012; Pierobon and Akyildiz 2013). It also includes design, analysis, and computer simulations of higher-layer mechanisms of molecular communication (Lio and Balasubramaniam 2012; Felicetti et al. 2014). It further includes standardization efforts to establish molecular communication as a standard framework and to develop simulation tools (Bush et al. 2015).

Key Applications

Functional applications of molecular communication systems are anticipated in a variety of domains (Nakano et al. 2012).

- **Biomolecular sensing:** Specific molecules in the human body serve as biomarkers

for certain diseases or medical conditions. More detailed information such as the spatial distribution of molecules is potentially useful for in-depth diagnosis. For biomolecular sensing, bio-nanomachines may sense their environment, communicate with others, and collectively determine whether specific molecules exist in their environment. Alternatively, bio-nanomachines may transmit sensed information to external devices or control units for diagnosis of their environment (Rogers and shung Koh 2016; Abdi et al. 2017).

- **Targeted drug delivery:** The delivery of drug molecules to target sites in the human body is expected in nanomedicine; it maximizes the efficacy of drug molecules and at the same time reduces potential side effects at nontarget sites. For drug delivery, bio-nanomachines may be embedded with drug molecules and either injected directly into target sites or intravenously to propagate to target sites. Bio-nanomachines may use molecular communication to collaborate to search for target sites, aggregate at the target sites, and release embedded drug molecules (Okaie et al. 2016; Wei et al. 2013).
- **Tissue regeneration:** In tissue development, biological cells communicate through synthesizing growth factor molecules and transmitting them into the environment. Growth factor molecules propagate in the environment and bind to cell surface receptors of the target cells. The concentrations and types of growth factor molecules modulate migration, proliferation, and differentiation of target cells, leading to the formation of a tissue structure. For the repair or construction of a tissue structure, bio-nanomachines made of living cells may be deployed in the human body. Bio-nanomachines use molecules to communicate with tissue-forming cells, while they divide and grow to help the tissue structure formation.
- **Internet of Bio-NanoThings:** Molecular communication systems may also be interfaced to and integrated with existing communication systems. Future mobile

phones or wearable devices may be integrated with bio-nanomachines capable of molecular communication for on-chip analysis of biochemical signals (e.g., molecules in blood or from sweat) (Hiyama et al. 2008b). Further, such devices and molecular communication systems may be integrated into the Internet to form the Internet of NanoThings (Akyildiz and Jornet 2010) or the Internet of Bio-NanoThings (Akyildiz et al. 2015).

Molecular Communication System Model

Figure 2 shows a model of molecular communication systems.

- **Bio-nanomachines** are sensors and actuators to form molecular communication systems. A bio-nanomachine is characterized with the three criteria: material, size, and functionality (Nakano et al. 2012). A bio-nanomachine is composed of biomaterials with or without non-biological materials. The size of a bio-nanomachine ranges from the size of a macromolecule to that of a biological cell (i.e., up to tens of μm). A bio-nanomachine implements a set of biochemical functionalities such as sensing a certain type of molecule to achieve application-dependent goals (e.g., biomolecular sensing). Examples of bio-nanomachines are genetically engineered biological cells.
- The **environment** is a three-dimensional space where bio-nanomachines are deployed. It is typically an aqueous environment (e.g., an internal environment of the human body), containing molecules and energy sources for bio-nanomachines to operate. The environment may also contain flow by which the operation of bio-nanomachines can be disturbed or alternatively enhanced (Kadloor et al. 2012; Tavakkoli et al. 2017). The environment may generate events or information of interest, or contain targets that generate such information. For example, in biomolecular sensing applications, a change of the human body into an abnormal state

Applications of Molecular Communication Systems, Fig. 2

Molecular communication system model

represents such an event, and in targeted drug delivery applications, cancer cells represent a target.

- **Sources** are entities in the environment that provide useful information. A source may be a bio-nanomachine or a group of bio-nanomachines that detects an event or target in the environment. A bio-nanomachine functioning as a source may detect an event or target biochemically and transmit the detected information by propagating information molecules to other bio-nanomachines or sinks.
- **Sinks** are entities that receive and collect information from bio-nanomachines or sources. A sink may be a bio-nanomachine or a group of bio-nanomachines that processes information and performs application-dependent functionalities such as releasing drug molecules. A sink may also be a conventional device capable of traditional communication (e.g., wireless communication) (Nakano et al. 2014). A sink may be made from materials that are not compatible with the environment and may be orders of magnitude larger than bio-nanomachines. A sink may function as a gateway that interconnects molecular communication systems with external systems. Examples of sink devices include implantable medical devices (Kiourti et al. 2014).

- **Noise** exists in molecular communication systems in various forms. The first type of noise is thermal noise. Due to thermal noise, molecular communication among bio-nanomachines and the operation of bio-nanomachines become stochastic. The second type of noise is physical noise. The high viscosity of the environment and fluid in the environment generate physical force, making it difficult for molecules to propagate and for bio-nanomachines to move. The third type of noise is caused by molecules existing in the environment or noise molecules. Due to noise molecules, molecular communication among bio-nanomachines, and the operation of bio-nanomachines can be disturbed.

Target Detection and Tracking

Okaie et al. (2016) describes key functionalities of molecular communication systems: target detection and tracking. Target detection is a functionality of molecular communication systems to detect a target in a given environment, while target tracking is aimed at detecting and tracking targets as they move. In nanomedical applications, targets can be disease sites, pathogens, infectious microorganisms, or biochemical weapons that represent a potential threat to the environment;

the timely detection of targets and tracking of targets are important to provide immediate treatments or further analysis of the environment.

The mechanisms for target detection and tracking proposed in Okaie et al. (2016) use two types of molecule: repellents and attractants. In search of a target, bio-nanomachines release repellents to quickly spread in the environment; the released repellents form the concentration gradient in the environment, bio-nanomachines move toward lower concentrations of repellents, and therefore they move away from each other to help their search process. Upon detecting a

target, they release attractants to recruit other bio-nanomachines in the environment toward the target location; the released attractants also form the concentration gradient in the environment, and bio-nanomachines move toward higher concentrations of attractants, namely, toward the target location.

Figure 3A illustrates target detection and tracking processes. Here (a) a group of bio-nanomachines is placed in an environment where a single target exists; (b) the group of bio-nanomachines first spreads in the environment using repellents, and as a result one of the

Applications of Molecular Communication Systems, Fig. 3

Target detection and tracking processes (Okaie et al. 2016). (A) A group of 100 bio-nanomachines is placed in an environment containing a single moving target. The bio-nanomachines communicate to distribute in the environment and aggregates around the target location. (B) A performance measure is given by the number of bio-nanomachines in the proximity of the target

bio-nanomachines detects the target; (c) this bio-nanomachine, upon detecting the target, starts releasing attractants, and nearby bio-nanomachines are thus attracted to the location of the bio-nanomachine (i.e., near the target); and (d) as the target moves, the group of bio-nanomachines uses repellents and attractants in the same manner to move and track the target. Figure 3B shows how the number of bio-nanomachines in the proximity of the target (namely, the number of bio-nanomachines within the circle in Fig. 3B) changes with time. The up-and-down behavior of the graph indicates target detection and tracking processes that bio-nanomachines perform.

Future Directions

The current molecular communication research focuses more on theoretical work than experimental one; wet laboratory experiments form an importance piece of future work. Wet laboratory experiments help identify practical issues and gain insight into biologically implementable designs of molecular communication systems. An objective would be to show the collective behavior of bio-nanomachines for a specific application such as target detection and tracking.

Wet laboratory experiments are however challenging for communication engineers, since experimental facilities are often not available to them. To solve this problem, tabletop molecular communication platforms are developed in (Farsad et al. 2013). Tabletop molecular communication platforms are built using macroscale devices such as electronic sprays and sensors, yet communication is performed by propagating molecules between the macroscale devices. Tabletop MC platforms help communication engineers gain experience in molecular communication and develop realistic models to analyze the unique features and characteristics of molecular communication systems.

Nonetheless, theoretical work remains important in future work. Biologically realistic modelling and computer simulations will help

reduce the cost and time required to carry out wet laboratory experiments. This will also help us understand the detailed dynamics of molecular communication, such as spatiotemporal concentrations of molecules, which is difficult to observe in wet laboratory experiments. Future work should therefore use an integrated approach of experimental and theoretical investigations in order to design and develop practical applications of molecular communication systems.

Data Privacy; Edge Computing; Fog Computing; Information Platform; Internet of Things (IoT); Smart City; Smart Community; Smart Community Services; Smart Infrastructure; Social Data Management; Vender and Consumer Relationship Management

Definition

Smart Infrastructure: A new style of infrastructure composed of conventional infrastructure and information and communication technologies (ICTs). Smart infrastructure refers to an efficient and highly functional infrastructure accomplished by ICT-based monitoring, control, and management.

Smart Community: An integration of smart infrastructures implemented in a certain region.

Introduction

A smart community is an integration of smart infrastructures implemented in a certain region. Each smart infrastructure may provide dedicated merits. However, the essential merit of a smart

community is community big data, which covers all infrastructures. To pursue the effective use of the community, big data is the key to the success of smart community projects. Therefore, data infrastructure is a necessity for a smart community. The information platform considering the safe data exchange and privacy preservation is described as a case study in Saitama City, Japan.

Smart Community

A smart city is an integration of smart infrastructures that are composed of conventional infrastructure and information and communication technologies (ICTs). Smart infrastructure refers to an efficient and highly functional infrastructure accomplished by ICT-based monitoring, control, and management (Nishi 2018). For example, a smart grid is composed of the interaction between the power grid and ICTs, and it accomplishes high-functioning grid operation and effective electricity usage. Smart transportation achieves automated drive and fare systems in logistics, cars, and road systems, which is also referred to as an intelligent transportation system (ITS). Smart agriculture improves the product value by controlling the growth of crops and the total efficiency of farm work. A smart government provides administrative services using the Internet to improve usability and operational efficiency. A smart city is an implementation of several smart infrastructures in a city. Similarly, a smart town and a smart island are implemented in a town and on an island, respectively. A smart community refers to a similar concept and is unrelated to the target region. Moreover, it is meaningless when these smart infrastructures are independently implemented in the target region. A smart community provides new services by integrating and linking information of different smart infrastructures. An example of this information integration is the efficient charge/discharge management for electric vehicles, combining data from an electric vehicle and the electric power system with traffic information. The intensive introduction of smart

infrastructures and strong information linkage enable the provision of more advanced services to communities. The penetration of Internet of Things (IoT) has created a large amount of data, and the success of the smart community project depends on the effective use of the data. The data management for a smart community is indispensable to provide attractive smart community services.

A smart community is described in the Smart Communities Guidebook (1997) by the State University of San Diego as “a geographical area ranging in size from neighborhood to a multi-county region whose residents, organizations, and governing institutions are using information technology to transform their region in significant ways. Co-operation among government, industry, educators, and the citizenry, instead of individual groups acting in isolation, is preferred. The technological enhancements undertaken as part of this effort should result in fundamental, rather than incremental, changes.” The ICT created a paradigm shift in infrastructures, and a significant amount of data processing and network transactions was generated. The data processing is primarily achieved in cloud services. However, the location of cloud causes obstacles to some services. The communication latency may cause a serious problem to hard real-time control applications. Open Fog (OpenFog Consortium 2018; Bonomi et al. 2012; Yi et al. 2015) proposed the placement of services closer to the terminal devices than the cloud for improving the efficiency of providing the services. Therefore, Fog would improve the service latency and improve the service distribution in the networks. Edge computing is used as a similar technology to Open Fog. Edge computing provides a computing environment at the edge of the Internet. This also means that the locations of the computing resources are closer to the IoT nodes than to the cloud. Data freshness is indispensable for some services, such as the ancillary service of power grids, and the automated car drive service. The study regarding Fog and Edge computing has become active as the discussions of new smart community services become popular. For data management,

FIWARE (<https://www.fiware.org>) (Ferreira et al. 2017) provides several types of data management API for smart community services. FIWARE provides various types of APIs to manage the smart community data; this shows the importance of data management, especially the multiple perspectives for the data management of smart city services. Herein, the smart community information platform from the perspective of its data management is focused and described.

Smart Community Data Specifications and Requirements

The requirements of smart city services are diverse. When providing smart city services, data specifications are required to provide the service. Several points for data specifications and requirements are used and described as follows.

Immediate data handling: Regarding time constraints, for example, ancillary services in a smart grid do not legally allow a delay of over 1 Hz. The IEC 61000-4 standard determines that the control delay has to be smaller than 10-ms intervals. Moreover, the IEC 61850-9-2 standard determines the tolerance of the delay to be less than 1 μ s. Thus, it is almost impossible to provide ancillary services as cloud services. However, it is necessary to accommodate new services that handle hard real-time system requirements, such as haptic communication for telemedicine and tactile sensing, which are sensitive to delay because they are required to transmit action-reaction force feedbacks to convey tactile sensations. This application also permits a 10-ms delay for maintaining stabilization in the control of its feedback control system (Anderson and Spong 1989). Cloud services cannot meet this need owing to their comparatively large communication delay.

Flexible data handling: Many protocols are proposed for communicating with IoT nodes. When focusing only on smart community protocols, especially the application layer, several examples can be provided: IEEE1888, IEEE1451, HTTP, MQTT, SEP2.0, Bluetooth (such as health thermometer profile, Bluetooth

Low Energy (BLE)), etc. In the application layer protocols, the primary purpose is to define the data formats. Therefore, server applications are required to support different protocols for receiving data from IoT devices, which differ in the types of application layer protocol. Moreover, new protocols and new data expression rules are successively developed to support the emerging smart community services. However, it is better to continually use conventional IoT devices that do not support new protocols because the replacement of all old IoT devices is costly. Moreover, it is typical that IoT terminals, which have similar sensors and functions, are installed redundantly at the same place owing to different protocols required to handle the data, and this poses a significant problem in the implementation of smart community services. It is important to design a smart community information infrastructure to address this problem.

Data cycle for improving QoL and QoS: For providing smart community services, it is essential to generate, store, process, and analyze the data, as well as foster the data to useful services, use the data through the services, change someone's behavior or control something using the data, and anonymize the data for its secondary use. Finally, the result of the behavior or control is measured by the sensors, and it creates the data again. This data cycle is shown in Fig. 1. This cycle enables the human behavior and machine

Architecture and Data Management for Smart Community Information Platform, Fig. 1 Smart community data cycle

control to be improved. Therefore, it improves the quality of life (QoL), such as the improvement in comfort or wellbeing, and the quality of service (QoS), such as the system efficiency or functionality. Thus, the smart city data infrastructure has to maintain the effective data cycle. The similar cycle is also discussed in ambient intelligence from a different perspective.

Data encapsulation: In the series of data processes, most parts of the process are achieved in the cloud, as shown in Fig. 2a. The use of cloud has the merit of low management cost. However, to use the cloud means to use a centralized system. Therefore, cloud services may cause a single point of failure and suffer from an advanced persistent threat. What types of countermeasures can be provided for it? It is strategically correct to prohibit gatherings and distribute people when the danger of terrorism is predicted. However, despite the repeated incidents of cyber terrorism, private data continue to be centrally managed in the cloud. It is also natural for people to

resist the revelation of personal information by moving these data from the cloud to their residential area. However, the service providers only consider their points of view and would force users to observe their service provision policy: “personal information must be managed in the cloud for providing services.” This situation is not desirable in the provision of smart community services. Private data should be encapsulated locally, and this encapsulation is effective from the perspective of protecting several types of attacks or threats, as shown in Fig. 2b. The cloud should provide a global service using abstract and unified information.

Data hierarchy: IoT devices send measured data to the cloud. On their way to the cloud, the data may pass a gateway at a smart house or smart building, or switches and routers at the internet providers, and finally, it will arrive at the service application programs in the cloud. As explained in data encapsulation, the data should be processed at an appropriate location when required

Architecture and Data Management for Smart Community Information Platform, Fig. 2 (a)

Conventional smart city data services. (b) Encapsulated smart city data services

Target Area	Narrow	Building <100 m	Town <10 km	City <100 km	Worldwide	Wide
Allowable Processing Delay	Short	Power System Stabilization Auto drive Collision Avoidance <10 ms		Facility Control <1 s Dynamic Pricing <30 min		Long
Calculation Cost Computing Platform	Small	Embedded Microcontroller	Server		Cluster Datacenter	Big
Anonymity	Weak	Plain	Weak Anonymization			Strong
			Strong Anonymization			
Amount of Data	Small	<KB	<MB		>GB	Big

Architecture and Data Management for Smart Community Information Platform, Fig. 3 Smart community service hierarchy

by the service. As shown in Fig. 3, the switches and routers as well as the gateways can become computational resources referred as edge and fog computing. The selection of the appropriate computational resources requires appropriate indexes, and the typical indexes are shown in the figure. When the services are provided in a gateway, it focuses on narrow space service provisioning and short-range communications, e.g., an indoor environment, and the amount of calculation cost and computing platform can be small because the required data amount is small. Anonymity is a new and important index, as given in data encapsulation. The gateway is often connected with IoT devices and handles the raw data generated by the devices. Contrastingly, the services provided in the cloud can use anonymized data, and vice versa, as explained in data encapsulation. The Edge or Fog computing environment provides a balanced environment between the gateway and cloud. By using these indexes and the differentiated environment, data can be stored at an appropriate network location and processed at an appropriate network location. Moreover, the needs of data processing chains on the Internet

are increasing. This chain of data processing is also discussed as service function chaining in network function virtualization (NFV) (Trajkovska et al. 2017). This data chain is important in providing services using the data. Figure 4 shows the mapping of promising smart community services according to the indexes. For example, HVAC control is provided in a building and may use private information. Electricity exchange service is provided in the city area, and the price can be defined using generalized information. Additionally, the service applications have to select the best location.

IoT data security: The risk of IoT terminals being hacked has increased in the recent years. Hence, the maintenance of security levels must be ensured. However, most IoT terminals have low computing and power capacities. Therefore, it is difficult to facilitate better resistance to cyber-attacks using complicated protocols to add new functionalities. Moreover, introducing additional security software, or new protocols, is undesirable from the viewpoint of power consumption and system cost. Thus, it is necessary to design an information infrastructure to address these

Architecture and Data Management for Smart Community Information Platform, Fig. 4 Mapping of smart community services considering service locations (Nishi 2018)

problems. Namely, the network system should provide new security services for IoT devices and locally stored data.

Private data handling: The protection of private information is important in smart community services because the data generated by residents for receiving smart community services could have privacy constraints. One of the protection methods is the aforementioned local data encapsulation. However, it is desirable to share the data for secondary use. This secondary use of data is the most promising service in the future smart community. Anonymization technology is key for the safe sharing of private data. If the data are perfectly anonymized and any type of private data is not extracted from the anonymized data, it is safe but is not useful for smart community services. The balance between difficulty in revealing private information and the usefulness in providing services is important. For achieving the balance at the highest level, the appropriate anonymization method must be designed and selected for each data service. Medical records, smart meters, locations,

and other data will have their respective suitable anonymization methods. The development of an anonymization method is indispensable. Moreover, watermarking technology for anonymized data is indispensable (Nakamura et al. 2017). In data service, the information of user rights must be managed, such as who generates the data, who uses the data, and what the purpose is. Watermarking technology can include the information in the anonymized data. The watermark in anonymized data can prevent data leakage by tracing the data leakage and protect the user rights holders.

Data ownership: Who possesses the data? Although this is a simple question, it is sometimes difficult to answer because the ownership and stakeholders of data are easy to entangle and handover. Moreover, the national speculations have worsened this situation. The General Data Protection Regulation (GDPR) was issued, and it provided a new stage of data management from the perspective of data privacy. In consideration of these situations, flexible data ownership management is required. Regarding the style of ser-

A

Architecture and Data Management for Smart Community Information Platform, Fig. 5 Vendor and consumer relationship management

vice provision, vendors have to manage the consumers; vendors draft contracts with consumers for providing services and provide reasonable prices for the services, in which the vendors aim to maximize both their benefit and the consumer satisfaction. In this contract, the vendors request the disclosure of private data. This is called consumer relationship management (CRM). Contrastingly, new trend requires an alternative relationship management between vendors and consumers such that the consumer can manage the vendors' services. This is called vendor relationship management (VRM). A user may think that a certain service is useful and worth providing the user's private data to the service vendor for a more efficient service. Meanwhile, the user may think that the service is enough to use as a trial and not worth providing the private information. In this case, the data management system will anonymize the data to preserve privacy. For attaining the flexible service relationship management between vendors and users, vendor and consumer relationship management (VCRM) is proposed (Niwa and Nishi 2017). Figure 5 shows the structure of VCRM. Both the vendor and consumer manage the database, which stores the information of the service provider or who the data user. A relationship is established when a contract of providing and receiving a service is engaged. The relationship is managed by its dedicated database, and the database has various information, such as the method and level of data anonymization, target area of service, location to be processed, service provider, service user, expi-

ration date, constraints for providing services, required computational power, required latency, and amount of data. VCRM manages these data and verifies the integrity with real use.

Smart Community Information Platform (SCIP)

The fusion of Fog/Edge, gateway, and cloud are appropriate as a desired future direction. However, their current shortfalls must be compensated. Therefore, an information mechanism called authorized stream contents analysis (ASCA) was proposed (Nishi 2018). ASCA is a mixed mechanism of software and hardware for supporting service provision. It supplies a method to process the information flowing through a communication network on intermediate communication devices. ASCA reconstructs the TCP stream on the device, decodes the SSL using the key shared with the cloud service, decodes Chunk and Gzip, executes string matching and the extraction function using regular expression rules, and subsequently sends the analyzed result of the stream to the dedicated service process. ASCA can modify the stream contents directly, under the constraint of the buffer size. When using 128 G of memory, it can analyze more than two million TCP streams simultaneously without the limitation of the TCP stream length by employing a dedicated context-switch technology. ASCA on a general enterprise server can provide 20

Gbps of processing performance using hardware accelerators, such as DPDK for the accelerating network throughput using userland zero-copy communication, HyperScan on the Intel Xeon Processor for accelerating the string matching function, and Intel QuickAssist Technology for accelerating the throughput of the encryption, decryption, compression, and decompression.

A service application using ASCA on a Fog/Edge terminal can process the network stream and provide dedicated services at an intermediate location on the route to the target in the cloud. This does not require any modification of the IoT terminals; the destination IP address of the data stream can maintain its original IP address of the target in the cloud. Moreover, ASCA provides the functionality to modify the stream contents, enabling the direct removal or anonymization of private information at the intermediate nodes. NEGI (Takagiwa and Nishi 2015) is an original library created for ASCA. It is designed with no acceleration and can therefore be utilized in any Linux-based environment, including an ARM-based embedded platform. The Intel Xeon platform can achieve 1 Gbps of streaming. DooR is a hardware accelerated library of the ASCA, and it achieves a 20-Gbps stream process. The proposed smart community information platform (SCIP) uses NEGI or DooR as basic libraries for stream processing. On these ASCA basic libraries, the user and service provider can design their services as a Docker container (Miura et al. 2017). Docker is a virtualized environment for executing application programs, and it reduces the cost of launching and terminating application software, compared with the conventional virtual machine environment. Because Docker provides a virtualized environment isolated from the host machine, the zero-copy architecture including the DPDK is not available for the application software as a Docker container. Therefore, Docker's shared memory option is used to communicate with a DPDK-supported NIC via shared memory to cope with this problem.

ASCA can handle the aforementioned smart community data specifications and requirements. ASCA provides a transparent environment as

network nodes. Because ASCA can monitor or modify a network stream at any point, it enables immediate data handling using zero-copy communication and hardware accelerators. It can also offer flexible data handling because it can provide services at the intermediate nodes on the Internet and change a communication protocol transparently. When ASCA is used as a basic library in the smart community data platform, it can be the key device for rotating the data cycle for improving the QoL and QoS. All the given functions in Fig. 1 can be achieved or measured using service applications with ASCA. Transparent data encapsulation can be achieved by designing the data firewall of the data anonymization application on the ASCA. Moreover, the hierarchical design of the ASCA-based encapsulation enables the data hierarchy. The firewall function and antivirus function on ASCA-supported devices can provide IoT data security. By implementing the appropriate applications on the ASCA, private data can be handled and the data can be anonymized. VCRM can be an application of ASCA. Therefore, either the user or the service provider can define and modify the relationship at any time. This feature adopts the opt-in and opt-out of data registration. The default value is given as the opt-in. The on-demand modification of the relationship achieves the opt-out.

Another important point is the mobility of the service applications. The initial allocation to an appropriate location and the subsequent execution of a service should ideally occur automatically, and be migrated as necessary, without the need for an explicit migration request. Executing this effectively requires managing several resources and activities, including memory, storage, CPU, communication, task allocation, and distribution, to manage the Docker containers with service applications. Thus, a mechanism for resource management that performs functions similar to the basic functions of an operating system is necessary. This resource management system is called the SCIP OS. Some basic functions of the SCIP OS resemble those of the orchestrator for Docker containers. However, the orchestrator only considers the management of the Docker containers, whereas the SCIP OS focuses on

the service applications more broadly from the perspectives of service feasibility, IoT feasibility, and future feasibility. Moreover, ASCA enabled wireless station can be a center of local data manager in the wireless environment. It gathers data from sensor nodes and offers a variety of benefits to local services in the reachable range of its wireless signals.

System Demonstration

The data anonymization and watermark insertion application of UDCMi, a smart town project in Misono Town, Saitama City, Japan, was demonstrated at the Global City Team Challenge EXPO (<https://pages.nist.gov/GCTC/>). This application uses the smart metering of smart houses in UDCMi. As a smart community service, a lifestyle recommendation service for eco-life is provided as a nudge service. In this demonstration scenario, the smart meter sends the data to the cloud, and the nudge report was automatically generated using machine-learning technology. En route to the cloud, the data are also captured, anonymized, and watermarked at the gateway by ASCA. The extension of the function of IoT devices was proven, and the effectiveness of the nudge report using anonymized data was compared with the other report using raw data.

Conclusion

Data-oriented smart community services are indispensable for the sustainable advancement of smart cities. The proposed smart community information platform is a system considering the given data specification and requirements. The complexity of data handling at the network infrastructure will be increased according to the development of a society structure. However, an information platform maximizing the flexible data management can solve various regional problems, including urbanization problems. The improvement of QoL and QoS, i.e., the ultimate goal of a smart community, is not achieved

by a single metric but by an interoperable data approach including the residents' behavior change and machinery control that enables hopeful societies to be established. Further developments of the architecture and data management of the smart community information platform are expected.

Definitions

HetNets are seen as new network paradigm evolutions to the fifth-generation wireless systems, which can cost-efficiently improve system coverage, capacity, latency, and so on.

Historical Background

With the explosive increase in mobile data traffic, operators have to continuously improve network performance. As a promising solution, the Het-Net is a new technology that can cost-efficiently improve system coverage and capacity (Peng et al. 2015a). Communication nodes with high transmit power, such as MBSs, are deployed for large coverage and high capacity, while LPNs, such as SCAPs, help to supply service in the coverage of some hotspots. By deploying additional LPNs within the local-area range and bringing LPNs closer to end-UEs, HetNets can potentially improve spatial resource reuse and extend the coverage, thus allowing future cellular systems to achieve higher data rates while retaining the uninterrupted connectivity and seamless mobility of cellular networks.

The LPN is identified as one of the key components to increase the capacity of cellular networks in dense areas with high traffic demands. When traffic is clustered in hotspots, such LPNs can be combined with HPN to form a HetNet. HetNets have advantages of serving hotspot customers with high bit rates through deploying dense LPNs, providing ubiquitous coverage, and delivering the overall control signalings to all UEs through the powerful HPNs. Actuarially, too dense LPNs will incur severe interference, which restricts performance gains and commercial developments of HetNets. Therefore, it is critical to control interference through advanced signal processing techniques to fully unleash the potential gains of HetNets. The CoMP transmission and reception is presented as one of the most promising techniques in 4G systems. Unfortunately, CoMP has some disadvantages in real networks because its performance gain depends

heavily on the backhaul constraints and even degrades with increasing density of LPNs. Further, it was reported that the average SE performance gains from the uplink CoMP in downtown Dresden field trials were only about 20% with non-ideal backhaul and distributed cooperation processing located on the base station.

To overcome the SE performance degradations and decrease the energy consumption in dense HetNets, a new paradigm for improving both SE and EE through suppressing inter-tier interference and enhancing the cooperative processing capabilities is needed in the practical evolution of HetNets. Meanwhile, cloud computing technology has emerged as a promising solution for providing high energy efficiency together with gigabit data rates across software-defined wireless communication networks, in which the virtualization of communication hardware and software elements place stress on communication networks and protocols.

To achieve these goals, the C-RAN has been proposed as a combination of emerging technologies from both the wireless and the information technology industries by incorporating cloud computing into RANs (Peng et al. 2016a). C-RANs have come with their own challenges in the constrained fronthaul and centralized BBU pool. A prerequisite requirement for the centralized processing in the BBU pool is an interconnection fronthaul with high bandwidth and low latency. Unfortunately, the practical fronthaul in C-RANs is often capacity and time-delay constrained, which has a significant decrease on SE and EE gains.

Consequently, H-CRANs are proposed in Peng et al. (2014) as cost-effective potential solutions to alleviating inter-tier interference and improving cooperative processing gains in HetNets through combination with cloud computing. The motivation of H-CRANs is to enhance the capabilities of HPNs with massive MIMO and simplify LPNs through connecting to a “signal processing cloud” with high-speed optical fibers. As such, the baseband datapath processing and the radio resource control for LPNs are moved to the cloud server so as to take advantage of cloud computing capabilities.

Unfortunately, H-CRANs are still challenging in practice. First, since the location-based social applications become more and more popular, the traffic data over the fronthaul between RRHs and the centralized BBU pool surges a lot of redundant information, which worsens the fronthaul constraints. Besides, H-CRANs do not take full advantage of processing and storage capabilities in edge devices, such as RRHs and “smart” UEs, which is a promising approach to successfully alleviating the burden of the fronthaul and BBU pool. Moreover, operators need to deploy a huge number of fixed RRHs and HPNs in H-CRANs to meet the requirements of peak capacity, which makes a serious waste when the volume of delivery traffic is not sufficiently large.

To solve such challenges in H-CRANs, revolutionary approaches involving new RAN architectures and advanced technologies need to be explored. Fog computing is a term for an alternative to cloud computing that puts a substantial amount of storage, communication, control, configuration, measurement, and management at the edge of a network, rather than establishing channels for the centralized cloud storage and utilization (Bononi et al. 2012). Inspired by the advanced characteristics of fog computing and to alleviate the existing challenges of H-CRANs and take full advantages of local caching, the F-RAN architecture has been proposed in Peng et al. (2016b).

In this chapter, we are motivated to make an effort to offer a comprehensive survey on system architectures, key techniques, and future trends in heterogeneous cellular networks, including HetNets, H-CRANs, and F-RANs ‘in addition, all the abbreviations are listed (Table 1).

Foundations

The Architecture of Traditional HetNets

To provide a high-speed performance for cell-edge users, a hierarchical HetNet architecture Fig. 1 has been proposed for converging multiple LPNs and supporting unicast and multicast services simultaneously, where the coverage areas are divided into three layers: hierarchical

Architectures, Key Techniques, and Future Trends of Heterogeneous Cellular Networks, Table 1 Abbreviations in this chapter

3GPP	Third generation partnership project	JR	Joint reception
4G	Fourth generation	JT	Joint transmission
BBU	Baseband unit	LPN	Low power node
CNN	Convolutional neural network	LTE	Long-term evolution
CN	Core network	MBS	Macro base station
CoMP	Coordinated multi-point	MIMO	Multiple-input-multiple-output
CS/CB	Coordinated scheduling/coordinated beamforming	PHY layer	Physical layer
CRSP	Collaborative radio signal processing	QoE	Quality of experience
CRRM	Collaborative radio resource management	QoS	Quality of service
C-RAN	Cloud radio access network	RAN	Radio access network
DL	Downlink	RF	Radio frequency
DRL	Deep reinforcement learning	RNN	Recurrent neural network

HetNet	Heterogeneous network	WLAN	Wireless local area network
HPN	High power node		

Architectures, Key Techniques, and Future Trends of Heterogeneous Cellular Networks, Fig. 1 HetNet architecture for E-UTRAN systems

cooperative basic layer, homogeneous cooperative enhanced layer, and heterogeneous cooperative extended layer. For the hierarchical cooperative basic layer, UEs may be located near the BS; high-speed service is supported due to the utilizations of high-order modulation and coding schemes for the unicast services and hierarchical modulation schemes with unequal error protection space-time code for the multicast service. In the homogeneous cooperative enhanced layer, cooperative homogeneous diversity gain can be achieved, where UEs may be located near a cell boundary. For the heterogeneous cooperative extended layer, heterogeneous cooperative diversity gain guarantees the convergence and interworking of multiple RANs.

The Architecture of H-CRANs

Similarly with the traditional C-RAN, As shown in Fig. 2, a huge number of RRHs with low energy consumptions in H-CRANs cooperate with each other in the centralized BBU pool to achieve high cooperative gains. Only the front RF and simple symbol processing functionalities are implemented in RRHs, while the other important

baseband physical processing and the procedures of the upper layers are executed jointly in the BBU pool. Sequently, only partial functionalities in the PHY layer are incorporated in RRHs, and the model with these partial functionalities is denoted as PHY_RF in Fig. 2.

However, different from C-RANs, the BBU pool in H-CRANs is interfaced to HPNs for mitigating the cross-tier interference between RRHs and HPNs through the centralized cloud computing-based cooperative processing techniques. Further, the data and control interfaces between the BBU pool and HPNs are added and denoted by S1 and X2, respectively, whose definitions are inherited from the standardization definitions of 3GPP. Since the voice service can be provided efficiently through the packet switch mode in 4G systems, the proposed H-CRAN can support both voice and data services simultaneously, and the voice service is preferred to be administrated by HPNs, while the high-data packet traffic is mainly served by RRHs.

Compared with the traditional C-RAN architecture, the proposed H-CRAN alleviates the fronthaul requirements with the participation

Architectures, Key Techniques, and Future Trends of Heterogeneous Cellular Networks, Fig. 2 System architecture of H-CRANs

of HPNs. Owing to the incorporation of HPNs, the control signalling and data symbols are decoupled in H-CRANs. All control signalling and system broadcasting information are delivered by HPNs to UEs, which simplifies the capacity and time-delay constraints of the fronthaul links between RRHs and the BBU pool, and can make RRHs active or sleep efficiently to save the energy consumption. Further, some burst traffic or instant messaging service with a small amount of data can be efficiently supported by HPNs. The adaptive signalling/control mechanism between connection-oriented and connectionless is supported in H-CRANs, which can achieve significant overhead savings in the radio connection/release by moving away from a pure connection-oriented mechanism. For RRHs, different transmission technologies in the PHY layer can be utilized to improve transmission bit rates, such as IEEE 802.11 ac/ad, millimeter wave, and even optical light. For HPNs, the massive MIMO is one potential approach to extend the coverage and enrich the capacity.

The Architecture of F-RANs

In the proposed F-RAN architecture shown in Fig. 3, the F-APs and F-UEs in the

terminal layer and network access layer constitute the fog computing layer, which are capable of conducting local caching, signal processing, and radio resource management. In the terminal layer, adjacent F-UEs can communicate with each other through the D2D mode or the F-UE-based relay mode. For example, F-UE13 and F-UE11 can communicate with each other with F-UE12 helping relay the signal, while F-UE11 and F-UE12 can operate in D2D mode to transmit data directly. In the network access layer consisting of F-APs and HPNs, HPNs are responsible for delivering control signalling to F-UEs, and F-APs are used to forward and process the received data. In addition, the data between F-APs and the BBU pool in the cloud computing layer is transmitted over fronthaul links, while HPNs are interfaced to the BBU pool with backhaul links for coordinations. The traditional X2/S1 interface for the backhaul link is backward compatible with that defined in 3GPP standards for LTE and LTE-Advanced systems.

Different from H-CRANs, a large number of CRSP and CRRM functions originally located in the cloud computing layer are shifted to F-APs and F-UEs, which alleviates the burden

Architectures, Key Techniques, and Future Trends of Heterogeneous Cellular Networks, Fig. 3 System model for implementing F-RANs

on the fronthaul and BBU pool. Meanwhile, the limited caching in F-APs and F-UEs can make some requests served locally. The benefit of this enhancement is significant, considering that the location-based social applications are becoming popular and much redundant information over the fronthaul links will worsen the fronthaul constraints. Furthermore, local caching, local signal processing, and local radio resource management can better satisfy the low latency requirement of some applications in 5G era.

Cooperative Spatial Processing

To boost the SE and EE performance of HetNets, the inter-tier interference should be properly handled. In the PHY layer, this interference can be mitigated by inter-tier CoMP transmission. The CoMP technique is aimed at enhancing the performance of cell-edge UEs. By the coordination between transmissions of adjacent cells, the CoMP can effectively suppress the adjacent cells' interferences when applied in UL or DL. Specifically, all access nodes can jointly decode transmitted signals from UEs in UL via JR while allocate transmission power to different UEs in a network MIMO manner with optimal precoding matrices, i.e., JT and CS/CB (Access 2010). It should be noted that the main difference between JT and CS/CB is that the data of each UE is transmitted by only one access node in CS/CB, while multiple cooperative nodes serve each UE simultaneously in JT. In Lee et al. (2012), it is demonstrated that JT and CS/CB can improve the performance of cell-edge UEs by 100% and 30%, respectively, compared to multiuser MIMO.

However, the backhaul transmission will incur latency for coordination in practice, and meanwhile the number of quantization bits for the exchanged information is limited, which will both degrade the performance of CoMP. The impacts of non-ideal backhaul are investigated in Xia et al. (2013), and it is concluded that the backhaul latency will affect the coverage and normalized throughput. Moreover, it is shown that the coverage and throughput achieved by CoMP zero-forcing beamforming decrease almost linearly with the average latency growing from zero. Even worse, when the latency exceeds

60% of the fading coherence time, the scheme does not have any benefit. Furthermore, the large number of cooperative cells does not essentially lead to better performance. On the contrary, it is shown that the number of coordinated cells should be kept fairly small in HetNets.

Radio Resource Management

To maximize the SE and EE performances of HetNets, the multidimensional radio resources should be optimized, including power allocation, subchannel allocation, and user association. However, because of the involvement of integer variables like subchannel allocation indicator and the existence of inter-tier and intra-tier interference, multidimensional radio resource allocation in HetNets is always non-convex, making the optimization problem hard to solve. To deal with the non-convexity, there are generally two kinds of ways. One is using heuristic algorithms which are suitable for finding the near-optimal solutions to NP-hard problems. The other one is to transform these non-convex problems into convex problems by different methods, and then the primal problems can be solved by settling the corresponding convex problems. In Peng et al. (2015b), the author focuses on maximizing EE by jointly allocating the resource block and transmit power for a heterogeneous cloud radio access network. Due to the non-convexity of the primal problem, the author tackles the primal problem by solving its dual problem aiming to minimize the Lagrange function of the primal problem which is always convex by definition. Moreover, since the primal problem satisfies the time-sharing condition, zero duality gap holds. Thus, the non-convex primal problem can be equivalently transformed into a convex optimization problem, i.e., its dual problem.

Furthermore, to achieve better global performance, it is very important to consider both the conventional physical layer performance metrics and the traffic delay in the upper layer. As a simple framework to deal with delay-aware RRM optimization problems, the Lyapunov optimization approach has been commonly adopted in HetNets. In Urgaonkar and Neely (2012), the Lyapunov optimization approach is utilized to

solve the problem of opportunistic cooperation in a two-tier HetNet. The access nodes would like to maximize their own throughput under average power constraints by optimizing access admission, cooperation decision, and power control. The obtained online control algorithm can stabilize the traffic queue without requiring any knowledge of the traffic arrival rates. While in Chen and Lau (2013), a two-stage queue-aware cross-layer resource management algorithm is proposed by minimizing drift-plus-utility. The cross-layer RRM consists of a queue-aware limited CSI feedback filtering optimization stage over a long timescale and an SINR-based optimal user scheduling stage over a short timescale. The utility is defined as the average feedback cost, and a large parameter V reduces the average CSI feedback at the cost of a larger average queue length.

Self-Organizing HetNets

Due to the ever-increasing number of radio resource management functionalities, it is impractical to manually adjust resource management parameters in a multidimensional parameter scenario. Faced with this issue, SON techniques have attracted a lot of attentions from both industry and academia. Generally speaking, the self-organizing capability of HetNets can be divided into three components: self-configuration, self-optimization, and self-healing. By using SON, the network configuration, installation, coverage, capacity, spectrum, and quality can be automatically managed and optimized taking into account target QoS performance, interference level, signal strength, traffic pattern, and so on.

To take full advantages of both centralized and distributed SON architectures, the author in Peng et al. (2013) proposes a hybrid SON architecture, and differences between traditional homogeneous networks and HetNets are discussed in terms of self-configuration like prediction-based radio resource configuration as well as self-optimization including mobility robustness optimization and energy saving. Moreover, it should be noted that time-varying traffic load makes the deployment of

completely self-organized HetNets nontrivial. Hence, the features of SON coordination in HetNets should be emphasized. Specifically, the graph-based decision framework proposed in Gelabert et al. (2014) can be adopted to enable efficient interaction and coordination of SON mechanisms, where the interaction and conflict relationship between multiple SON mechanisms are described by the metric event and action graph. Based on this proposed framework, the strategy-based SON coordination for HetNets can be easily implemented for a given event or a combination of events.

Key Applications

HetNets are the key to satisfying the diverse and stringent performance requirements in future wireless networks.

Future Directions

Access Slicing in HetNets

As a cost-efficient solution to support diverse use cases in the 5G era, network slicing enables the provision of networks in an as-a-service fashion. However, current studies mainly concentrate on CN-based slicing, and the impact of the characteristics of RANs is not well considered. To get a more effective network slicing solution, the author in Xiang et al. (2017) proposes an enhanced network slicing approach in F-RANs, termed as access slicing. The proposed access slicing architecture is featured with a centralized orchestration layer, a slice instance layer, and the information awareness capability to guarantee diverse QoS and QoE requirements. Although the above work makes a big step for network slicing, several challenges exist for its implementation. First, as stated in Xiang et al. (2017), the information awareness allows the access slice orchestration layer makes intelligent decisions on slice instance creation and resource management. Nevertheless, more specifications should be investigated like the types of information needed, the frequency for collecting information, and the way

of slice instance configuration based on processed information. Second, resource allocation between multiple slices should be investigated to fully utilize the resources of HetNets to meet diverse performance requirements. Such a problem can be very challenging, since it is basically a multi-objective optimization problem. Meanwhile, besides allocating radio resource, some slices also need caching resource and computation resource, which incurs an extra challenge.

HetNets Driven by Deep Learning

As an important technology for enabling artificial intelligence, deep learning has been successfully applied in many areas, including computer vision and speech recognition, and has drawn a lot of attentions of researchers in the wireless communication area. In Cao et al. (2017), a learning framework is proposed in which a CNN and an RNN are used to extract features in spatial domain and time domain from raw information collected by wireless networks, respectively, and this manner avoids identifying features manually. Taking the derived features as state input, DRL is adopted to control wireless networks intelligently, and the superiority of the proposal is verified by applying it to mobility management in WLAN. However, to apply deep learning in HetNets, more studies should be conducted. For example, more theoretical analysis should be done to provide guidelines on the architecture design of neural networks and the selection of hyper-parameters. Furthermore, the infrastructure of HetNets needs to be upgraded to support the implementation of deep learning algorithms, especially at the network edge to facilitate real-time network optimization and control.

Area Spectral Efficiency of Ultradense Networks

Guoqiang Mao
University of Technology Sydney, Sydney,
NSW, Australia

Synonyms

Area spectral efficiency; Ultradense networks

Definition

Area spectral efficiency refers to the data rate that can be achieved per unit bandwidth and in a unit area of the wireless network. It has the unit of b/s/Hz/m^2 or b/s/Hz/km^2 .

Historical Background

Network densification has been the main driver of wireless network capacity increase in the past and will play an even more crucial role in the development of the next generation mobile communication systems (5G). Network densification refers to the deployment of more base stations (BSs) and wireless access points per unit area and the associated technological advances to support such densification. There are three primary ways of increasing the wireless network capacity: (1) adding more spectrum, (2) enhancing spectral efficiency through advanced communication techniques, and (3) enhancing spatial reuse of frequency spectrum through network densification. The area spectral efficiency (ASE) is a major metric to measure the efficiency in the spatial

reuse of frequency spectrum. According to a study by Webb (Henderson 2007), among the 1-million-fold increase in wireless network capacity achieved in 50 years from 1950 to 2000, $15\times$ improvement was achieved from a wider spectrum, $5\times$ improvement from better Medium Access Control (MAC) and modulation schemes, $5\times$ improvement by designing better coding techniques, and an astounding $2700\times$ gain through network densification and reduced cell sizes. As we move to the next generation mobile communication systems and seek further capacity increases, network densification, manifested through heterogeneous and ultradense networks, will play an even more important role. First, the combined amount of spectrum available for licensed mobile broadband and unlicensed Wi-Fi is scarce. Spectrum approaching millimeter wavelengths is more abundant but is yet to be proven for cellular and Wi-Fi use due to difficulty in penetration and supporting significant mobility (Andrews et al. 2016a; Kutty and Sen 2016). Second, the scope for enhanced spectral efficiency may be limited as many current wireless systems are already running at a spectral efficiency close to the performance limit prescribed by the Shannon. Therefore, mobile operators have increasingly turned to network densification and small cell technology to meet the $1000\times$ capacity increase expected on 5G. Small cells are now deployed in massive numbers (Small Cell Forum 2016), which drives the paradigm shift into ultradense networks. Ultradense networks feature a very dense deployment of BSs and wireless access points.

Foundations

The ASE and wireless network capacity can be used interchangeably in the sense that the total capacity achieved by a network deployed in a given geographical area and using a specific amount of bandwidth is equal to the ASE times the size of the area and the amount of bandwidth. It is of crucial interest to investigate how the ASE

varies as more and more BSs are deployed and the network becomes denser and denser.

The SINR Invariance Principle for Low-to-Medium BS Density

Until recently, there was widely held belief that the ASE, or equivalently the network capacity, may increase indefinitely as the network densifies (Haenggi et al. 2009; Andrews et al. 2011). This view has been underpinned by the so-called SINR (signal-to-interference-plus-noise ratio) invariance principle, which is valid for a low-to-medium BS density. We use the following example to illustrate the SINR invariance principle. Consider a set of BSs deployed on an infinite plane, and number these BSs according to their distances to the origin such that the k -th nearest BS has a distance of l_k . Further assume that all BSs transmit at the same fixed power P_t and the wireless signal experiences standard power-law attenuation such that the received power at a distance d from the transmitter is $P_r(d) = P_t L d^{-\alpha}$, where L is a reference path loss at unit distance and α is the path loss exponent. For a “typical” user located at the origin and associated with its nearest BS, its SINR can be expressed as

$$\text{SINR} = \frac{P_t L l_1^{-\alpha}}{\sum_{k=2}^{\infty} P_t L l_k^{-\alpha} + \sigma^2}, \quad (1)$$

where σ^2 represents the noise power. Now consider scaling the distances between all BSs by a factor of t . The density of BSs will increase by a factor of $\frac{1}{t^2}$. Further assume that noise power is negligible, which is valid in an interference-limited regime where most wireless networks now operate in. The SINR then becomes

$$\begin{aligned} \text{SINR} &= \frac{P_t L (t l_1)^{-\alpha}}{\sum_{k=2}^{\infty} P_t L (t l_k)^{-\alpha} + \sigma^2} \\ &\simeq \frac{P_t L (t l_1)^{-\alpha}}{\sum_{k=2}^{\infty} P_t L (t l_k)^{-\alpha}} \\ &= \frac{l_1^{-\alpha}}{\sum_{k=2}^{\infty} (l_k)^{-\alpha}}, \end{aligned} \quad (2)$$

i.e., the SINR is invariant with the increase of BS density.

The SINR invariance principle implies that as the network densifies and the distances between transmitters and receivers reduce, the increase in interference will be counterbalanced by the increase in the desired signal. Consequently, the SINR will stay approximately the same. The principle suggests that other things being equal, the spectral efficiency, or equivalently the capacity, per BS cell is invariant as network densifies. Therefore, from the network perspective, the ASE, or equivalently the overall network capacity, will linearly increase with the number of cells per unit area; from the user perspective, as each user maintains the same SINR but shares its BS with an ever-smaller number of other users, each user can achieve approximately linear growth in its achievable data rate as BSs are added, until the limit of one user per cell is reached. The SINR invariance principle is not affected by the BS layout, transmit power, shadowing and fading distributions, and path loss exponent (Andrews et al. 2016b).

Area Spectral Efficiency for Ultradense BS Regime

Recent research suggested however that the SINR invariance principle may no longer apply when the BS density becomes very large and that there may exist a limit in network densification, beyond which further densification will not bring the expected linear increase in capacity and may even reduce the capacity (Ding et al. 2015, 2016a,b; Ge et al. 2016; Liu et al. 2016a,b; Andrews et al. 2016b; Zhang and Andrews 2015). Specifically, by incorporating those effects that have negligible impacts on the ASE when the BS density is small or moderate but become dominant factors determining the ASE when the BS density is very large, it was shown that the ASE may either exhibit a sublinear increase with the BS density, or reduce at certain region of the BS density, or even monotonically reduce to zero beyond a certain BS density threshold.

In Ding et al. (2015, 2016a,b), and Ge et al. (2016), researchers considered the impact of non-line-of-sight (NLoS) and line-of-sight

(LoS) transmissions on the ASE. NLoS and LoS transmissions are ubiquitous in wireless communications. Other things being equal, as the distance between a transmitter and a receiver increases, the probability that their direct LoS path gets blocked increases and the converse. NLoS transmissions will generally suffer much higher path loss than LoS transmissions. Specifically, by employing a 3GPP-endorsed LoS/NLoS probability model given below

$$\Pr^L(x) = \begin{cases} 1 - \frac{x}{d_1}, & 0 < x \leq d_1 \\ 0, & x > d_1 \end{cases}, \quad (3)$$

where $\Pr^L(x)$ is the probability that a transmitter and a receiver separated by a distance x experience LoS transmission, $1 - \Pr^L(x)$ is the probability that the same pair of transmitter and receiver experiences NLoS transmission, and d_1 is a parameter determining the decreasing slope of the linear function $\Pr^L(r)$. Ding et al. (2016a) investigated the variation of the ASE with the BS density, shown in Fig. 1. The ASE is determined using the following equation

$$ASE = \lambda \Pr(\text{SINR} \geq \gamma_0) \int_{\gamma_0}^{\infty} \log_2(1+x) f_{\text{SINR}}(x) dx \quad (4)$$

where λ is the BS density, γ_0 is the SINR threshold required for establishing a connection, $f_{\text{SINR}}(x)$ is the probability density function of the SINR, and the term $\log_2(1+x)$ comes from the Shannon capacity formula. In the literature, the ASE has also been calculated using the following formula $ASE = \lambda \Pr(\text{SINR} \geq \gamma_0) \log_2(1+\gamma_0)$, which reflects the fact that some wireless systems may not be able to explore the extra SINR above the SINR threshold γ_0 to boost the data rate.

Figure 1 shows that when LoS/NLoS transmissions are considered, the ASE exhibits not only quantitatively but also qualitatively different trends with the BS density, compared with the case that does not consider the distinction of LoS and NLoS transmissions. Specifically,

1. when the BS density is small, the ASE quickly increases with the BS density because the network is generally noise-limited and adding more BSs immensely benefits the ASE by reducing the transmission distance between the BS and the mobile user (MU). Most transmissions in this regime are NLoS transmissions; however the transmission between a MU and its desired BS has a higher probability of being LoS transmission, and as the BS density further increases, this probability increases to a non-negligible value. Therefore, in this region, the ASE considering LoS/NLoS transmissions is higher than that without considering LoS/NLoS transmissions, but their trend is the same;
2. when the network is dense enough, i.e., greater than 20 BS/km² in Fig. 1, the growth of the ASE with the BS density, when considering LoS/NLoS transmissions, becomes flat or even exhibits a decrease (for $\gamma_0 = 3$ dB and $\gamma_0 = 6$ dB), which is distinctly different from that predicted without considering LoS/NLoS transmissions. This can be explained by the so-called NLoS-LoS transition effect. Particularly, in this region, the transmissions between MSs and their desired BS are already dominated by LoS transmissions but in the beginning signals from interfering BSs, are mainly NLoS transmissions suffering higher loss. As BS density further increases and the distances between a MU and BSs, including both the desired BS and interfering BSs, further reduce, signals from interfering BSs start to transit from NLoS transmissions to LoS transmissions. Consequently, as the BS density increases, interference experiences a larger increase compared with the desired signal, causing the SINR to reduce sharply in this region. Therefore, the ASE remains largely flat with the increase in BS density or may even reduce;
3. when the network becomes very dense, i.e., greater than 100 BS/km² in Fig. 1, the dominant interfering BSs have completed their NLoS-LoS transitions. Both the desired signal and the dominant interference are now

Area Spectral Efficiency of Ultradense Networks,

Fig. 1 The variation of the ASE with the BS density at various SINR thresholds. Both the case considering the coexistence of NLoS and LoS transmissions and the case without considering the coexistence of NLoS and LoS transmissions are shown. The case without considering the coexistence is plotted using the result in Andrews et al. (2011) and assuming $\alpha = 3.75$, $P_t = 24$ dBm, $\sigma^2 =$

-95 dBm, and $L = 10^{-14.54}$. The case considering the coexistence of NLoS and LoS transmissions is obtained assuming $d_1 = 300$ m, $P_t = 24$ dBm, $\sigma^2 = -95$ dBm, $\alpha = 2.09$, and $L = 10^{-10.38}$ for LoS transmissions and $\alpha = 3.75$ and $L = 10^{-14.54}$ for NLoS transmissions. These parameters are chosen following 3GPP recommendations

LoS transmissions. However, non-dominant interfering BSs further away from the MS may still experience the NLoS-LoS transition effect. Therefore, in this region, the SINR may still reduce modestly with the increase in BS density. This modest decrease in the SINR combined with the increase in the BS density causes the ASE to increase but at a rate below that predicted without considering LoS/NLoS transmissions.

Open data at Ofcom, an independent regulator and competition authority for the UK (<http://sitefinder.ofcom.org.uk/search>), shows that in some dense urban regions in the UK, the BS density already exceeds 10 BS/km². As we move into the regime of ultradense networks, we are bound to pass through the aforementioned second region. Therefore, it is important to consider the effect of LoS and NLoS transmissions when analyzing the ASE of ultradense networks.

In 2016b, Liu et al. investigated the ASE from a different perspective by considering the transition from far-field to near-field radio propagation which may be triggered as the BS density increases to a very large value. Specifically, it is well known that wireless signal attenuates faster at larger distances. In a region close to the transmitter, the signal may suffer little attenuation, while this attenuation sharply increases as the distance from the transmitter becomes large. Based on some field measurements, they proposed the following multi-slope BPM model to better capture the signal attenuation

$$g_N^B(\{\alpha_n\}_{n=0}^{N-1}; x) = \eta_n (1 + x^{\alpha_n})^{-1},$$

$$R_n < x \leq R_{n+1}, \quad (5)$$

where x denotes the distance from the transmitter to the receiver, R_n separates the attenuation func-

tion into several distinct regions, and α_n denotes the path loss exponent for $R_n < x \leq R_{n+1}$, $\eta_0 = 1$, and $\eta_n = \prod_{i=1}^n \frac{1+R_i^{\alpha_i}}{1+R_i^{\alpha_{i-1}}}$. As signals are attenuated faster at larger distances, $\alpha_n < \alpha_{n+1}$ holds. Using the model, they predicted that the ASE may monotonically decrease to zero when the BS density increases beyond a certain critical threshold. When the SINR threshold $\gamma_0 = 20$ dB, this critical BS density lies between 5000 – 25,000 BS/km² depending on the values of α_i ; when $\gamma_0 = 0$ dB, this critical BS density lies between $2 \times 10^5 - 3 \times 10^5$ BS/km². In a separate work (Zhang and Andrews 2015), Zhang and Andrews used a dual-slope (power-law) path loss function to model the different radio propagations in a region close to the transmitter and in a region far away:

$$l_2(\alpha_1, \alpha_2; x) = \begin{cases} x^{-\alpha_0} & x \leq R_c \\ \eta x^{-\alpha_0} & x > R_c \end{cases}, \quad (6)$$

where $\eta = R_c^{\alpha_1 - \alpha_0}$, $R_c > 0$ is the critical distance, and α_0 and α_1 are the near- and far-field path loss exponents with $0 \leq \alpha_0 \leq \alpha_1$. Using the model, they predicted that the ASE grows linearly with the BS density λ if $\alpha_0 > 2$, scales sublinearly with rate $\lambda^{2-\frac{2}{\alpha_0}}$ if $1 < \alpha_0 < 2$, and decays to zero if $\alpha_0 < 1$. It is worth noting that compared with extensive studies on far-field propagation models, surprisingly little is known about near-field radio propagation. Therefore, the models in (5) and (6) are plausible. However, a

common insight revealed in their work (Zhang and Andrews 2015; Liu et al. 2016b) is that the ASE exhibits quantitatively and qualitatively different trends with the BS density λ when the different propagation conditions in the near-field and in the far-field are considered.

In Ding and Perez (2016) and Gruber (2016), researchers considered the impact of some geometric conditions on the ASE. Specifically, in Ding and Perez (2016), Ding and David Lopez investigated the impact of antenna height on the ASE by considering a scenario where the BS antenna height is kept constant when its density increases. They showed that when the height of the BS relative to the MU is maintained at a constant value of 8.5 m, the ASE may peak when the BS density increases to ~ 15 BS/km² and then starts to monotonically decrease to zero as the BS density further increases. In comparison, when the impact of this height is ignored, the ASE may increase monotonically toward infinity. Their result can be intuitively explained using Fig. 2, which shows that while the impact of antenna height may be small at small BS density, its impact may play a dominant impact on the ASE in an ultradense network with a large BS density. In 2016, Gruber considered the geometric constraints limiting the BS deployment locations. Specifically, by considering that BSs can only be deployed along the two sides of the street, some distinctly different results on the ASE were obtained compared with that assuming BSs can be deployed randomly and anywhere in the street. It is worth noting that while some assumptions

Area Spectral Efficiency of Ultradense Networks, Fig. 2 An illustration of the different impacts of the antenna height as the distance between MU and BS changes. When the distance d between the MU and BS is large, the impact of the relative height between BS antenna, h_a , and MU, h_p , on the propagation distance x

is small and negligible. When the BS density increases to a very large value and hence the distance d reduces to a small value, the impact of $h_a - h_p$ on the propagation distance x is no longer negligible and may even be the dominant factor determining x

used in these studies are quite plausible, e.g., as the density of BS increases, one would expect that the BS size and height also reduce instead of being constant; the insight revealed in these studies holds: as we move into the ultradense regime, such geometric restrictions as physical dimensions of transmitters and receivers and deployment restrictions on BSs that previously have small or negligible impact on the ASE may now become dominant factors in the consideration.

In summary, distinct from conventional low-to-medium density networks, in ultradense networks, impacts of LoS/NLoS transmissions, the different radio propagation conditions in the near-field and far-field of BSs, and network geometric constraints may play an important role in determining the ASE.

Key Applications

The ASE is a fundamental performance metric of ultradense networks and more general wireless networks. The ASE determines the capacity that can be achieved by a wireless network and measures the efficiency in the spatial reuse of frequency spectrum. Knowledge of the ASE helps to guide the design and deployment of wireless networks.

Artificial jamming schemes; Physical layer security

Definition

Cellular communications and networks are particularly vulnerable to eavesdropping attacks due to the opened and broadcasting nature of wireless channels. Due to the rapid development of cellular networks and wireless business, the security issue has attracted a lot of attention. Physical layer security takes the advantages of channel randomness nature of transmission media to achieve communication confidentiality, which is the most important and interesting topic of privacy communication technologies. Artificial noise (AN) or jamming signals with MIMO technologies are supposed to implement physical layer security and enhance secrecy capacities in cellular networks, where AN signals along with confidential data confuse potential eavesdroppers via utilizing orthogonal spaces provided by transmit antennas. In these AN-based schemes, message streams were sent in a multiplexing mode via all eigen-subchannels (positive eigenvalue channels) at desired directions, and the AN signals can be transmitted to the null spaces (zero eigenvalue channels) of desired directions, so that they do not affect the desired user, while eavesdropper channels are degraded with a high probability. This chapter introduces a physical layer security review, covering the information theory and physical layer security schemes based on MIMO

technologies, and provides an overview on the state-of-the-art works on the AN-based scheme along with conclusions and future research directions.

Historical Background

The origin of physical layer security research can be traced back to Wyner's definition of an information-theoretic secrecy capacity (Wyner 1975), which is a maximum message transmission rate in confidential communications. Compared to conventional cryptography that works to ensure all involved entities to load proper and authenticated cryptographic information, physical layer security technologies perform confidentiality functions without considering about how those security protocols are executed. In other words, it does not require to implement any extra security schemes or algorithms on other layers above the physical layer. In addition, the physical layer has the same confidentiality level with the one-time pad, which ensures its security performance. The concept of physical layer security has become more popular with the help of MIMO technologies, because these emerging technologies can improve the secrecy capacity massively via utilizing extra orthogonal spaces provided by multiple antennas.

Information Theory

Wyner implied that the intrinsic and unpredictable elements of physical channels, such as noises, interferences, and wireless fading, play central roles in protecting secure messages (Wyner 1975) and claimed that there exists a randomized codebook maximizing transmission rates that can achieve perfect secrecy where any eavesdroppers cannot get any information. The maximizing secrecy rate is defined as a secrecy capacity C_s as

$$C_s = \max_{V \rightarrow X \rightarrow YZ} I(V; Y) - I(V; Z), \quad (1)$$

where $I(\cdot; \cdot)$ denotes mutual information between V and Y and V is an auxiliary input

variable with a joint auxiliary input distribution $p(v)p(x|v)$. Given a discrete memoryless channel $P_{YZ|X}$, wiretap codes achieve the secrecy capacity via maximization over the choices of the joint distribution $P_{YZ|X}$, such that the Markov chain $V \rightarrow X \rightarrow YZ$ holds, which has been expected to completely address the underlying problem of that traditional cryptographic algorithms are vulnerable to quantum attacks.

In the last two decades, researchers have developed a significant amount of mathematical theories, such as secrecy capacity characterization, wiretap coding designs, wireless fading managements, etc. And the advancements in cellular technologies have improved physical layer security significantly, by exploring spatial diversities and multiplexing gains with the help of multi-antennas technologies.

Physical Layer Security Schemes Based on MIMO Technologies

From the traditional communication viewpoints, improving the link quality of the main channel is one of the most feasible approaches to improve the secrecy capacities with existing installations of cellular networks, because most of the cellular wireless communication technologies can improve the channel spectrum utilization, and if the eavesdropping channel spectrum utilization is unchanged, these traditional wireless communication technologies will undoubtedly improve the secrecy capacities. However, this viewpoint has a great security risk, i.e., the secrecy capacities are small if the eavesdropper has a better channel quality than the desired users. Therefore, current research insists on another viewpoint that jointly uses more degree of freedom of main channels and artificial randomness to protect messages while reduces the quality of eavesdropping channels. Prospectively, the randomness of multipath fading of a MIMO channel is stronger than a single channel. Multiplexing technologies of MIMO are promising ways to enhance the degree of freedom of main channels. And AN signals can interfere with eavesdroppers while they are sent into the null spaces of desired directions.

We briefly summarize MIMO-based physical layer security techniques of recent research in four categories, as in Fig. 1, including secure unitary beamforming, zero-forcing (ZF) beamforming, convex optimization-based precoding, and AN-based precoding. It is emphasized that a MIMO-based physical layer security scheme of cellular networks can combine multiple techniques.

As in Fig. 1a, unitary beamforming techniques use unitary matrices, semi-unitary matrices, or unitary vectors as transmit precoding, which is similar with traditional beamforming technologies of cellular networks. Unitary beamforming techniques send a message stream via multi-antennas to make it as close to the main channel direction as possible. ZF beamforming is shown in Fig. 1b, which is a secure beamforming technology based on ZF precoding, where the message stream is transmitted to a desired receiver via a shifted beamforming direction, which is orthogonal to the eavesdropper's channel. The illustrative diagram of CVX-based precoding can be seen in Fig. 1c. The problem of optimizing secrecy capacities is usually non-convex in MIMO systems, but Newton methods or Lagrangian dual transformations can be used to trap it in a local maximum problem and address the transmit covariance matrix optimization based on convex optimization tools. AN signals can be transmitted to the null spaces of desired directions, so that they do not affect the desired user, while an eavesdropper's channel is degraded with a high probability, as in Fig. 1d. This AN-based precoding exploits a fraction of the transmit power to send artificially generated noise signals, so the power for transmitting messages will be reduced.

AN-based schemes have been seen as promising methods because this type of techniques has two advantages. Firstly, there are no requirements on the condition of better main channels. Secondly, when the number of transmit antennas is larger the number of the eavesdroppers, the main channel state information (CSI) and precoding matrices of security schemes can be broadcasted to both legitimate receivers and eavesdroppers. We do not need to worry about the

Artificial Noise Schemes Based on MIMO Technology in Secure Cellular Networks, Fig. 1 Illustrative diagrams of four basic secure multi-antenna technologies. For simplicity, this sets two-dimensional diagrams and a

single message stream. (a) Secure unitary beamforming, (b) Zero-forcing precoding, (c) CVX-based precoding, (d) AN-based precoding (Liu et al. 2017a)

leakage of key precoding messages. More details of the second advantage can be seen in Liu et al. (2017b).

Artificial Noise Schemes

The section will introduce a general AN-based model, which is first provided in Liu et al. (2017b). Assuming t is the number of transmit antennas, messages are encoded in s (which is a variable) strongest eigen-subchannels based on ordered eigenvalues of Wishart matrices ($\mathbf{H}\mathbf{H}^\dagger$ or $\mathbf{H}^\dagger\mathbf{H}$, here, $\mathbf{H}$ is the main channel CSI matrix), while AN signals are generated in remaining $t - s$ eigen-subchannels. This scheme treats the number of eigen-subchannels for message streams, i.e., s , as an optimization objective that can be leveraged to optimize secrecy capacities.

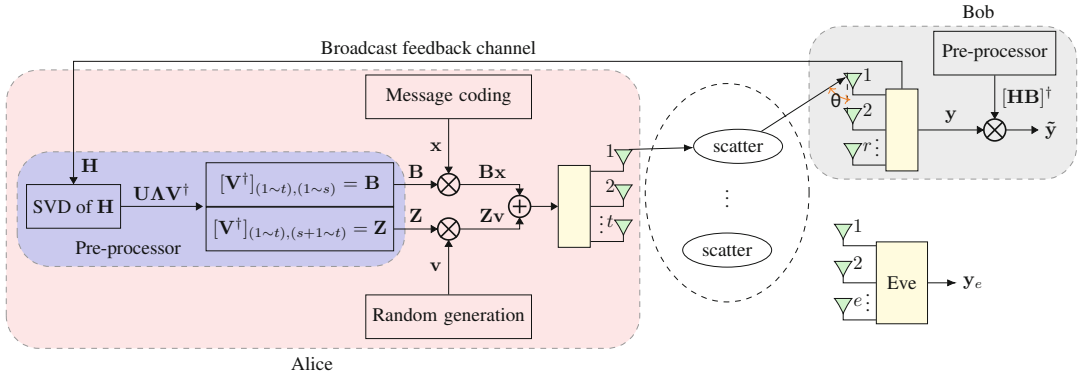

General AN-Based Model

Let us consider a MIMO communication system in the presence of correlated Rayleigh fading at receiver and eavesdropper sides. The system consists of a transmitter (Alice) with t transmit antennas, a legitimate receiver (Bob) with r receive antennas, and an eavesdropper (Eve) with e receive antennas, as shown in Fig. 2. Define $m = \max(t, r)$ and $n = \min(t, r)$. In general, the main channel between Alice and Bob and the wiretap channel between Alice and Eve are defined by receiver-side correlated complex Gaussian matrices $\mathbf{H} \in \mathbb{C}^{r \times t}$ and $\mathbf{H}_e \in \mathbb{C}^{e \times t}$,

whose elements obey distribution $\mathcal{CN}(0, 1)$. $\mathbf{R}_r \in \mathbb{C}^{r \times r}$ and $\mathbf{R}_e \in \mathbb{C}^{e \times e}$ are the receiver-side correlated channel matrices from Bob and Eve, respectively. Also assume that Alice knows full CSI of Bob via a broadcast feedback channel from Bob, including $\mathbf{H}$ and $\mathbf{R}_r$, but only knows the channel distribution information (CDI) of Eve and $\mathbf{R}_e$. Eve knows the CSI of all channels, including $\mathbf{H}$, $\mathbf{H}_e$, $\mathbf{R}_r$, and $\mathbf{R}_e$, where it is assumed that $t > e$.

In this AN-based scheme, there are s ($s \leq t$) message-sending eigen-subchannels, which are selected by Alice based on the CSI feedback from Bob. More specifically, Alice performs SVD of $\mathbf{H}^\dagger\mathbf{H} \in \mathbb{C}^{t \times t}$ in a preprocessor, whose output is a unitary matrix $\mathbf{U} \in \mathbb{C}^{t \times t}$, its Hermitian transpose form $\mathbf{U}^\dagger \in \mathbb{C}^{t \times t}$, and a diagonal matrix $\mathbf{\Lambda} \in \mathbb{R}^{t \times t}$, which consists of positive and zero eigenvalues of $\mathbf{H}^\dagger\mathbf{H}$. Then, Alice generates a message precoding matrix $\mathbf{B} \in \mathbb{C}^{t \times s}$, whose columns are the eigenvectors corresponding to the first to the s th largest eigenvalues of $\mathbf{H}^\dagger\mathbf{H}$, and an AN precoding matrix $\mathbf{Z} \in \mathbb{C}^{t \times d}$ ($s + d = t$), whose columns are the eigenvectors of the remaining eigenvalues of $\mathbf{H}^\dagger\mathbf{H}$.

Alice transmits $\mathbf{B}\mathbf{w} + \mathbf{Z}\mathbf{v}$ via t transmit antennas. It means that each antenna transmits a combination of message components and AN components, but the AN components can be eliminated by the preprocessor at Bob. In this way, we create a capacity difference between the main channels and wiretap channels. Note that $\mathbf{B}$ and $\mathbf{Z}$ are fixed semi-unitary matrices derived from $\mathbf{H}$. Hence, we have $\mathbf{B}^\dagger\mathbf{B} = \mathbf{I}_s$ and

Artificial Noise Schemes Based on MIMO Technology in Secure Cellular Networks, Fig. 2 Illustration of an artificial noisy MIMO wiretap channel model with receiver-side correlated Rayleigh fading. Alice has t transmit antennas, Bob has r receive antennas, and Eve has e

receive antennas. Assumed that Alice, Bob, and Eve have uniformly linear array antennas with d_u antenna spacing. θ represents AoA between a scattered path and the antenna array, which can be viewed as a random variable with enough scatterers, and θ follows a Gaussian distribution

$$\text{SVD}(\mathbf{H}^\dagger \mathbf{H}) = \begin{matrix} \boxed{\mathbf{U} : t \text{ rows } t \text{ columns}} \\ \begin{pmatrix} \textcircled{u_{11}} & \textcircled{u_{12}} & \textcircled{u_{13}} & \dots & \textcircled{u_{1t}} \\ \textcircled{u_{21}} & \textcircled{u_{22}} & \textcircled{u_{23}} & \dots & \textcircled{u_{2t}} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \textcircled{u_{t1}} & \textcircled{u_{t2}} & \textcircled{u_{t3}} & \dots & \textcircled{u_{tt}} \end{pmatrix} \end{matrix} \times \begin{matrix} \boxed{\mathbf{\Lambda} : t \text{ rows } t \text{ columns}} \\ \begin{pmatrix} \textcircled{\lambda_{11}} & 0 & \dots & 0 \\ 0 & \textcircled{\lambda_{22}} & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & \textcircled{\lambda_{tt}} \end{pmatrix} \end{matrix} \times \mathbf{U}^\dagger$$

for messages
 $\mathbf{B} = \{\mathbf{u}_1, \mathbf{u}_2\}$

for AN
 $\mathbf{Z} = \{\mathbf{u}_3, \dots, \mathbf{u}_t\}$

- 1) The $r \times t$ matrix $\mathbf{H}$ is a channel matrix with t transmit antennas and r receive antennas.
- 2) Two antenna arrays $\{\mathbf{u}_1, \mathbf{u}_2\}$ corresponding to two maximum eigenvalues λ_{11} and λ_{22} are allocated for message transmission.
- 3) Remained antenna array $\mathbf{u}_3, \dots, \mathbf{u}_t$ corresponding to the remained eigenvalues is allocated for AN signal transmission.
- 4) By the precoding $\mathbf{B}$ and $\mathbf{Z}$, the information signal $\mathbf{w}$ and AN signal $\mathbf{s}$ are encoded as $\mathbf{B}\mathbf{w}$ and $\mathbf{Z}\mathbf{s}$.

Artificial Noise Schemes Based on MIMO Technology in Secure Cellular Networks, Fig. 3 An example of this AN precoding scheme with $s = 2$

$\mathbf{Z}^\dagger \mathbf{Z} = \mathbf{I}_d$. An example of AN precoding scheme with $s = 2$ is illustrated in Fig. 3.

Theorem 1 *The AN signal can be eliminated at Bob if and only if $[\mathbf{H}\mathbf{B}]^\dagger \mathbf{H}\mathbf{Z} = \mathbf{0}$ (Liu et al. 2017b).*

Theorem 2 *The AN signal cannot be eliminated at Eve if and only if $t > e$, $[\mathbf{H}\mathbf{B}]^\dagger \mathbf{H}_e \mathbf{Z} \neq \mathbf{0}$, and $[\mathbf{H}_e \mathbf{B}]^\dagger \mathbf{H}_e \mathbf{Z} \neq \mathbf{0}$ (Liu et al. 2017b).*

According to CSI matrix $\mathbf{H}$ and the preprocessing method, the received signals at Bob and

Artificial Noise Schemes Based on MIMO Technology in Secure Cellular Networks, Table 1 Secrecy metrics with their conditions

Measures	Symbols	Conditions
Instantaneous secrecy capacity	C_s	$\mathbf{H}_e$ is available and optimal input distribution.
Average secrecy capacity	$\tilde{C}_s$	$\mathbf{H}_e$ is unavailable and optimal input distribution
Instantaneous secrecy rate	R_s	$\mathbf{H}_e$ is available and Gaussian distribution input
Average secrecy rate	$\tilde{R}_s$	$\mathbf{H}_e$ is unavailable and Gaussian distribution input

Eve can be expressed as

$$\mathbf{y} = \mathbf{H}\mathbf{B}\mathbf{w} + \mathbf{H}\mathbf{Z}\mathbf{v} + \mathbf{n}, \quad (2)$$

$$\mathbf{y}_e = \mathbf{H}_e\mathbf{B}\mathbf{w} + \mathbf{H}_e\mathbf{Z}\mathbf{v} + \mathbf{n}_e, \quad (3)$$

respectively. Here, $\mathbf{w}$ is a transmitted signal of the desired user, and $\mathbf{v}$ is a random AN signal. Both $\mathbf{w}$ and $\mathbf{v}$ are circularly symmetric complex Gaussian vectors with zero means and its covariance matrices $P/t\mathbf{I}_s$ and $P/t\mathbf{I}_d$, respectively, where P is the average transmit power constraint. For simplification, we distribute total power to each antenna evenly. $\mathbf{n}$ and $\mathbf{n}_e$ are additive white Gaussian noise (AWGN) vectors with their covariance matrices $\mathbf{I}_r$ and $\mathbf{I}_e$, respectively.

Bob can eliminate the AN signal $\mathbf{v}$ by preprocessing ($[\mathbf{H}\mathbf{B}]^\dagger \mathbf{H}\mathbf{Z} = \mathbf{0}$) the received signal $\mathbf{y}$ as

$$\tilde{\mathbf{y}} = [\mathbf{H}\mathbf{B}]^\dagger \mathbf{y} = \mathbf{A}_s \mathbf{w} + \tilde{\mathbf{n}}, \quad (4)$$

where $\tilde{\mathbf{n}} = [\mathbf{H}\mathbf{B}]^\dagger \mathbf{n} \in \mathbb{C}^{s \times 1}$ is an AWGN vector with its distribution $\mathcal{CN}(\mathbf{0}, \mathbf{A}_s)$. $\mathbf{A}_s \in \mathbb{R}^{s \times s}$ is a diagonal matrix formed by the first to the s th eigenvalues of $\mathbf{H}^\dagger \mathbf{H}$. In the elimination process, the received signal multiplied by a fixed matrix will not change its capacity. Even if we consider the worst case that Eve has the knowledge of $\mathbf{H}$, $\mathbf{H}_e$, $\mathbf{B}$, and $\mathbf{Z}$, the AN signal still degrades Eve's channel because Eve cannot eliminate the AN signal because $t > e$, $[\mathbf{H}\mathbf{B}]^\dagger \mathbf{H}_e \mathbf{Z} \neq \mathbf{0}$, and $[\mathbf{H}_e \mathbf{B}]^\dagger \mathbf{H}_e \mathbf{Z} \neq \mathbf{0}$, as in **Theorem 1**.

Secrecy Metric

The secrecy capacity and secrecy rate are important measures of AN-based schemes. Here, four expressions are provided to represent the instantaneous secrecy capacity, the average secrecy capacity, the instantaneous secrecy rate, and the average secrecy rate, respectively. These mea-

sures are fit in with different conditions as in Table 1

Instantaneous Secrecy Capacity

In a MIMO wiretap channel model, while Bob has the knowledge of $\mathbf{H}$, $\mathbf{H}_e$, $\mathbf{R}_r$, and $\mathbf{R}_e$, the instantaneous secrecy capacity is

$$C_s = \max_{p(\mathbf{w}), p(\mathbf{v})} \{I(\mathbf{w}; \mathbf{y}) - I(\mathbf{w}; \mathbf{y}_e)\}, \quad (5)$$

where $I(\mathbf{w}; \mathbf{y})$ is the mutual information between information variables $\mathbf{w}$ and received vector $\mathbf{y}$ at Bob and $I(\mathbf{w}; \mathbf{y}_e)$ is the mutual information between information variables $\mathbf{w}$ and received vector $\mathbf{y}_e$ at Eve. And the maximization is taken over all possible input distributions of $p(\mathbf{w})$ and $p(\mathbf{v})$. However, it is hard to begin the optimization process when $\mathbf{H}_e$ is unavailable.

Average Secrecy Capacity

Assuming that the communication lasts longer enough to experience all channel states, to average out the randomness of C_s when only CDI of $\mathbf{H}_e$ is available, we remark that C_s is a function of $\mathbf{H}_e$, and then, the average secrecy capacity is

$$\tilde{C}_s = \max_{p(\mathbf{w}), p(\mathbf{v})} \{I(\mathbf{w}; \mathbf{y}) - I(\mathbf{w}; \mathbf{y}_e | \mathbf{H}_e)\}, \quad (6)$$

where $I(\mathbf{w}; \mathbf{y} | \mathbf{H}_e) = \mathbb{E}_{\mathbf{H}_e}[I(\mathbf{w}; \mathbf{y}_e)]$ is the expected value of the conditional mutual information between $\mathbf{w}$ and $\mathbf{y}_e$ for given $\mathbf{H}_e$. And the maximization is taken over all possible input distributions of $p(\mathbf{w})$ and $p(\mathbf{v})$.

Instantaneous Secrecy Rate

Either in the instantaneous expression or in the average expression, it is hard to find optimal distributions of $p(\mathbf{w})$ and $p(\mathbf{v})$ to maximize the

secrecy capacity. Here follow the convention in Liu et al. (2017b, 2015), and use the secrecy rate instead of the secrecy capacity with Gaussian input alphabets and Gaussian AN, i.e., both $\mathbf{w}$ and $\mathbf{v}$ are circularly symmetric complex Gaussian vectors. In this case, the instantaneous secrecy rate can be expressed as

$$R_s = [C_m - C_w]^+, \quad (7)$$

where $[x]^+ = \max(x, 0)$. C_m and C_w are

$$C_m = \log_2 \det(\mathbf{I}_r + (P/t)\mathbf{H}_1\mathbf{H}_1^\dagger), \quad (8)$$

$$C_w = \log_2 \det\left(\mathbf{I}_e + \frac{(P/t)\mathbf{H}_2\mathbf{H}_2^\dagger}{(P/t)\mathbf{H}_3\mathbf{H}_3^\dagger + \mathbf{I}_e}\right),$$

respectively. Here, $\mathbf{H}_1 = \mathbf{H}\mathbf{B} \in \mathbb{C}^{r \times s}$, $\mathbf{H}_2 = \mathbf{H}_e\mathbf{B} \in \mathbb{C}^{e \times s}$, and $\mathbf{H}_3 = \mathbf{H}_e\mathbf{Z} \in \mathbb{C}^{e \times d}$. However, the instantaneous secrecy capacity is hard to be calculated by Eq. (7) in the absence of Eve's CSI.

Average Secrecy Rate

Assuming the CDI of $\mathbf{H}_e$, the average secrecy rate can be expressed as

$$\begin{aligned} \tilde{R}_s &= \mathbb{E}_{\mathbf{H}_e} [C_m - C_w]^+ \\ &\geq C_m - \mathbb{E}_{\mathbf{H}_e} [C_w]. \end{aligned} \quad (9)$$

Equation (9) gets an equality if and only if the secrecy rates are always positive over all channel states. Since AN signals are used to jam the wiretap channels, the average secrecy rate is always nonnegative. From **Lemma 1** in the Appendix, $\mathbf{H}_2$, $\mathbf{H}_3$, and $\mathbf{H}_4$ are complex Gaussian matrices with their distributions

$$\mathbf{H}_2 \sim \mathcal{CN}_{e,s}(\mathbf{0}, \mathbf{R}_e \otimes \mathbf{I}_s), \quad (10)$$

and

$$\mathbf{H}_3 \sim \mathcal{CN}_{e,d}(\mathbf{0}, \mathbf{R}_e \otimes \mathbf{I}_d), \quad (11)$$

respectively. Hence, the expected value of average secrecy rates can be calculated by Monte Carlo simulations with Eve's CDI.

Artificial Noise Schemes Based on MIMO Technology in Secure Cellular Networks, Fig. 4 AoA model with respect to a uniform antenna array

Correlated Matrices

The correlated matrices $\mathbf{R}_r$ and $\mathbf{R}_e$ can affect all the secrecy metrics of an AN-based system. As in Bolcskei et al. (2003), a correlated matrix $\mathbf{R}$ (generalized for $\mathbf{R}_r$ and $\mathbf{R}_e$) is a function of AoA (defined by θ) distribution. Here consider an AoA model with respect to a uniform antenna array based on 3GPP 3GP (2003), as shown in Fig. 4, where the AoA model belongs to a Gaussian distribution, the mean AoA of θ is $\bar{\theta}$, and the RAS (variance) of θ is δ . Then, we get the following simple model for the correlated coefficient $[\mathbf{R}]_{u,v}$, which is

$$\begin{aligned} [\mathbf{R}]_{u,v} &= \exp \left\{ -j2\pi(u-v)d_u \cos \bar{\theta} \right\} \\ &\times \exp \left\{ -\frac{1}{2}(2\pi\delta(u-v)d_u \sin \bar{\theta})^2 \right\}, \end{aligned} \quad (12)$$

where $u \in \{1, \dots, r\}$ and $v \in \{1, \dots, r\}$ are the receive antenna index numbers. According to the parameters from 3GPP standard 3GP (2003), $\bar{\theta}$ is set in the range $[0^\circ, 100^\circ]$ and δ in the range $[5^\circ, 35^\circ]$, respectively. Assume that all antennas form a uniformly linear antenna array with $d_u = d_{\min}/\omega$, where $d_{\min}$ is the normalized minimum distance and ω is the wavelength. In the wiretap channel model, $\mathbf{R}_r$ and $\mathbf{R}_e$ have the same structure as $\mathbf{R}$. Here define the mean AoA at Bob and Eve as $\bar{\theta}_r$ and $\bar{\theta}_e$, respectively, and define the RAS at Bob and Eve as δ_r and δ_e , respectively.

Artificial Noise Schemes Based on MIMO Technology in Secure Cellular Networks, Fig. 5 Average secrecy rates in terms of the number of Bob's antennas

Simulations

Simulation results are provided to investigate joint impacts of the number of antennas and the number of selected message-sending eigen-subchannels on the average secrecy rates.

Figure 5 shows the relationship between the average secrecy rates and the number of Bob's antennas. In the case of adequate transmit antennas, i.e., $t:r = \kappa \geq 2$ and $e = r$, the average secrecy rates increase with an increasing number of Bob's antennas in both high ($P = 30$ W) and low SNR ($P = 3 \times 10^{-4}$ W) regions. In the case with a small number of transmit antennas and adequate receive antennas (here we set $t:r = \leq 1, s = 1$, and $e = t - 1$), we find that the average secrecy rates converge to a deterministic constant when e becomes large. It means that an increasing number of Bob's antennas bring in no benefit when Alice uses less antennas than Bob

and selects $s = 1$, i.e., uses a transmit diversity scheme.

Conclusion and Further Work

Physical layer security will play a critical role in the future security architecture of cellular communications. This research should keep competing with cryptography and quantum communications, which are believed to be the three major security architectures for cellular communication systems. AN-based schemes are seen as promising methods and now have produced a raft of fascinating and important results. However, these AN-based schemes are optimal only under the condition of that the number of transmit antennas is larger than eavesdropper antennas. When the number of transmitted antennas is constrained or even smaller than that of eavesdropper

antennas, AN-based schemes cannot get positive secrecy capacities or rates. This motivates us to design a better AN-based scheme. In addition, the secrecy capacity (rate) quantization is a great challenge in AN-based schemes. Without perfect CSI of eavesdroppers, it is hard for encoders to calculate instantaneous secrecy capacities or rates. And the influence of fading does not allow us to use a simple AWGN or Rayleigh channel model to calculate a secrecy rate. It seems that we need to investigate main and wiretap fading channels that belong to other models of cellular communications. At last, power allocation in cellular networks should be investigated further, because power allocation problems are usually non-convex ones with a lot of cellular users.

Appendix

Lemma 1 (Proved in Gupta and Nagar 1999) Define an $r \times t$ matrix $\mathbf{A} \sim \mathcal{CN}_{r,t}(\mathbf{0}, \mathbf{R} \otimes \mathbf{I}_t)$ as a receiver-side correlated central complex Gaussian matrix, and establish an independent $(t \times s)$ unitary matrix $\mathbf{B}$. We have

$$\mathbf{AB} \sim \mathcal{CN}_{r,s}(\mathbf{0}, \mathbf{R} \otimes \mathbf{I}_s), \quad (13)$$

where $s \in \mathbb{R}$ and $t \geq s$.

Key Applications

Artificial noise (AN) schemes based on MIMO technologies can be applied to various cellular scenarios. For example, Massive MIMO systems have an enormous number of antennas, which offer more degrees of freedom for wireless channels, and a more secure performance in terms of secrecy capacities and the number of AN beam-forming. The small cell base stations deployed as cooperative jammers in cellular networks can be used to provide well-designed AN signals. In addition, the long-term evolution advanced (LTE-A) system supports device to device (D2D) communications, which is defined as the direct communications between two mobile users via

shared radio resources with cellular users. D2D interference caused by the shared radio resources can be seen as AN signals to interfere with the illegitimate eavesdropper.

Definition

Asynchronous coordination technique is a communication approach that sensor nodes use different predetermined wake-up and sleep patterns for each cycle of network operations in order to achieve high energy efficiency and to guarantee network connectivity based on certain properties in linear algebra and optimization. No time synchronization is required in the network operations.

Historical Background

Underwater acoustic sensor networks (UWSNs) have attracted much research interest in recent years due to their wide range of potential applications such as marine environmental monitoring, undersea resources exploration, disaster monitoring and prevention, assisted location and navigation, and security monitoring

(Akyildiz et al. 2015). Early generation of UWSNs include the Acoustic Local Area Network (ALAN), which was deployed by the Woods Hole Oceanographic Institution (WHOI) in 1994 off the coast of Monterey, California (Catipovic et al. 1993). ALAN, aiming at long-term data acquisition and ocean monitoring, consists of a number of sensor nodes placed on the seafloor and one surface node attached to a buoy. The underwater sensor nodes located on the seafloor transmit data to the surface node via acoustic links. Data was transmitted to the onshore base station via a radio frequency link. Another example of UWSNs is Seaweb 2000 (Rice et al. 2000), which was one of the first multi-hop underwater acoustic networks. This project advanced the underwater communication technology to achieve near-realtime, synoptic observation of the underwater environment. In Seaweb 2000, 14 sensor nodes (to sense, collect, and relay data) were placed on the seafloor and three gateway nodes with buoys (to collect data from sensor nodes and transmit data to the onshore station) were deployed on the sea surface (Rice et al. 2002). A fundamental architecture of UWSNs is presented in Fig. 1. As shown in Fig. 1, underwater acoustic sensor nodes either directly report data to the surface node or transmit data to the sink node via multi-hop. The sink node aggregates data from different sensor nodes and then transmits to the surface node. The onshore base station will receive data from the satellite after the surface node reports collected data to the satellite.

Underwater acoustic communications consume more energy especially for long-range transmission (Zhang et al. 2015) compared with terrestrial communications. Furthermore, energy availability is limited in underwater acoustic communications because of the unchangeable and nonchargeable batteries in the sensor nodes. Frequently replacing sensor nodes generates high deployment cost, which is not realistic in long-term marine monitoring applications (Heidemann et al. 2012; Zhang et al. 2015). Therefore, unlike the high requirements of network throughput and packet delay, energy efficiency is a fundamental

Asynchronous Coordination Techniques, Fig. 1 The fundamental architecture of UWSNs

and significant issue when designing underwater network protocols.

An effective approach to energy saving is the wake-up coordination scheme. In the wake-up coordination scheme, each sensor node works periodically and has two modes of operations in each period: wake-up mode and sleep mode. In the wake-up mode, the transceiver is turned on for neighboring node discovery and data exchange (once the communication between a source node and destination node is established), whereas it remains off during the sleep mode so that energy consumption can be reduced. In general, the wake-up coordination scheme can be categorized into on-demand, synchronous, and asynchronous wake-up coordination schemes.

On-demand Wake-up Coordination Schemes

On-demand wake-up coordination scheme is a communication approach that each sensor node

is equipped with a low power radio module to wake up the node for communication. The wake-up time can be predetermined according to application requirements, network data traffic, and so on. For example, cooperative underwater multichannel media access control (MAC) protocol (CUMAC) is a typical protocol based on the on-demand wake-up coordination mechanism, which adopts two acoustic transceivers to be equipped for one sensor node (Zhou et al. 2012). The low-priced acoustic transceiver is used to detect the channel by sending and receiving tone signal. The other acoustic transceiver is for data transmission. The tone pulse sent by the low-price acoustic transceiver at a predetermined time arrives at different sensor nodes at different times. Sensor nodes can catch the tone pulse by the low-price acoustic transceiver at the right time and then wake up the acoustic transceiver to exchange data packets at proper time. Similar mechanisms can be referred in Syed et al. (2008) and Jurdak et al. (2010).

Synchronous Wake-up Coordination Schemes

Synchronous wake-up coordination scheme is a communication approach that all sensor nodes are time synchronized before data transmission so that each sensor node can wake up at the proper time to send or receive data. Also, sensor nodes can turn off their transceivers to conserve energy when there is no data to transmit or receive. For example, underwater wireless acoustic networks MAC protocol (UWAN-MAC) is a distributed scalable energy-efficient scheme based on synchronous wake-up coordination mechanism (Min and Rodoplu 2008). In the UWAN-MAC protocol, before data transmission, each sensor node broadcasts signaling packets (i.e., time stamp) which includes information about the amount of time in sleep mode during one cycle and records information transmitted by its neighboring nodes to achieve time synchronization among all sensor nodes. The time stamps guarantee that neighboring nodes would wake up at the correct time in order to receive data packets without the knowledge of the propagation delay. Similar protocols can be found in van Dam and Langendoen (2003) and Ye et al. (2004).

Asynchronous Wake-up Coordination Schemes

Unlike the on-demand and synchronous wake-up coordination schemes, asynchronous wake-up coordination schemes utilize different predetermined wake-up and sleep patterns for each cycle of network operations to achieve high energy efficiency and to guarantee network connectivity without time synchronization during the network operations. By using asynchronous wake-up coordination schemes, two sensor nodes are able to communicate with each other at least once in one cycle if they are in the communication range. Meanwhile, sensor nodes can sleep as long as possible to reduce energy consumption when they do not have data to transmit and to forward. In general, each sensor node works periodically. In one period, the operations of

each sensor node alternate between the wake-up mode and sleep mode. In the wake-up mode, the transceiver of the sensor node is turned on for neighboring node discovery and data exchange (once the communication between a source node and destination node is established). In the sleep mode, the transceiver of the sensor node remains off so that energy consumption can be reduced. Both the wake-up mode and the sleep mode may contain different numbers of time slots. A time slot is called an active slot when the sensor node operates in the wake-up mode and is called an inactive slot when the sensor node stays in the sleep mode. In this case, the operation status of a sensor node alternates between a predetermined number of active slots and inactive slots. To understand the diverse asynchronous wake-up coordination schemes, the following definitions and theorems are presented.

Preliminaries

Definition 1 (Quorum system) (Jiang et al. 2005) Let U be a universal set and $U = \{0, 1, 2, \dots, n - 1\}$. A quorum system Q is defined as a collection of non-empty subsets of U (e.g., G and H), which satisfies

$$\forall G, H \in Q, G \cap H \neq \emptyset. \quad (1)$$

For example, $U = \{0, 1, 2\}$, $Q = \{\{0, 1\}, \{0, 2\}, \{1, 2\}\}$ is a quorum system under U .

Definition 2 (Rotational closure property) (Jiang et al. 2005) A quorum system has the rotation closure property when

$$\begin{aligned} \forall G, H \in Q, i \in \{0, 1, 2, \dots, n - 1\}, \\ G \cap \text{rotate}(H, i) = \emptyset, \end{aligned} \quad (2)$$

where i is a nonnegative integer and $\text{rotate}(H, i) = \{(j + i) \bmod n | j \in H\}$.

For example, the quorum system $Q = \{\{0, 1\}, \{0, 2\}, \{1, 2\}\}$ under $\{0, 1, 2\}$ has the rotation closure property. However, the quorum system $Q' = \{\{0, 1\}, \{0, 2\}, \{0, 3\}, \{1, 2, 3\}\}$ under $U = \{0, 1, 2, 3\}$ has no rotation closure property

because $\{0,1\} \cap \text{rotate}(\{0,3\}, 3) = \emptyset$ (Jiang et al. 2005).

Definition 3 ($(Z_v, +)$ (Stinson 2004) $(Z_v, +)$ is a finite group of order v , where v is a positive integer.

Definition 4 (Cyclic difference set) (Stinson 2004; Choi and Shen 2011) Given a set D with v elements and k subset elements, $D : a_1, a_2, \dots, a_k \pmod{v}$ is called a (v, k, λ) –cyclic difference set in $(Z_v, +)$ if for every $d \neq 0 \pmod{v}$ there are exactly λ ordered pairs (a_i, a_j) , such that $a_i - a_j = d \pmod{v}$.

For example, $D = \{1, 2, 4\}$ is called a $(7, 3, 1)$ –cyclic difference set in $(Z_7, +)$.

Theorem 1

(Singer difference set) (Stinson 2004 ; Choi and Shen 2011) Let q be a prime power. Then there exists a $(q^2 + q + 1, q + 1, 1)$ –cyclic difference set in $(Z_{q^2+q+1}, +)$.

The cyclic difference sets can be constructed according to Theorem 1. For instance, $(7, 3, 1)$ –cyclic difference set when $q = 2$, $(13, 4, 1)$ –cyclic difference set when $q = 3$, $(21, 5, 1)$ –cyclic difference set when $q = 4$. More cyclic difference sets can be found in Appendix A of Stinson (2004).

Theorem 2

(Multiplier theorem) (Stinson 2004) Suppose there exists a (v, k, λ) –difference set D in an Abelian group $(Z_v, +)$ of order v . p is a multiplier of D if the following four conditions are satisfied: (1) p is prime; (2) $\gcd(p, v) = 1$, $\gcd$ is greatest common divisor; (3) $k - \lambda = 0 \pmod{p}$; and (4) $p > \lambda$.

According to Theorems 1 and 2, $p = 2$ is a multiplier of $(21, 5, 1)$ –cyclic difference set because 2 satisfies the four conditions in Theorem 2. Based on the multiplier, it is easy to construct two $(7, 3, 1)$ –cyclic difference sets: $\{1, 2, 4\}$ and $\{3, 5, 6\}$.

Quorum-Based Energy Conserving (QEC) Protocol

Figure 2 presents the basic idea of network operations in QEC. The white cube represents an inactive

Asynchronous Coordination Techniques, Fig. 2 The fundamental idea of QEC

tive slot and the black and gray cube are an active slot. When node u and node v each arbitrarily choose a row and a column from a square of size n , respectively, their active intervals would overlap for at least two active slots, e.g., the 10-th and the 34-th slots shown in this figure ($n = 7$). Furthermore, there exists at least one overlapped active slot if two sensor nodes adopt two different grid sizes (Chao et al. 2006). It is obvious that a large value of n can lead to better energy conservation (larger number of time slots in one period associated with larger number of inactive slots) but it would also increase the latency. The QEC (Chao et al. 2006) accommodates different traffic loads by varying the value of n and thus achieve a balance between energy efficiency and packet delay. The simulation results show that QEC can outperform IEEE 802.11 in terms of energy consumption.

Cyclic Difference Set (CDS)-Based Protocol

The CDS-based protocol determines the number and positions of active and inactive slots in one cycle using as Singer difference set of a (v, k, λ) –cyclic difference set, where v , k , and λ represent the total number of slots, the number of active slots, and the minimum number of overlapping active slots in one cycle, respectively (Zheng et al. 2003, 2006). The CDS-based protocol guarantees at least one active overlapping active slot between any two sensor nodes for any cyclic shift.

Asynchronous Coordination Techniques, Fig. 3 An example of the network operations in the CDS-based protocol followed (7,3,1)–cyclic different set

Figure 3 presents an asynchronous wake-up coordination schemes followed (7,3,1)–cyclic different set. In one period, a sensor node has seven time slots including three active slots and four inactive slots. The positions of active slots (i.e., black cubes) and inactive slots (i.e., white cubes) are determined by the (7,3,1)–cyclic different set. There exists at least one active overlapping slot between any two cycle shift for the cases of perfect and no alignment of time slot boundaries Zheng et al. (2006). That is, the network connectivity can be guaranteed and the energy consumption on idle listening is reduced as well. Furthermore, the CDS-based protocol conserves more energy on idle listening than that of the QEC protocol due to the minimum number of overlapping active slots is one between any cycle shift.

Extension of CDS-Based Protocols

The extension of CDS-based protocols aims to reduce more energy consumption by leveraging a longer cycle period with less active slots without sacrificing network connectivity.

Exponential adaptive CDS-based protocol (EACDS) and multiplicative adaptive CDS-based protocol (MACDS) are the two extensions of the CDS-based protocols (Choi and Shen 2011). The key idea of these two schemes is the use of hierarchical arrangements of sets with the Kronecker product (Anderson 1998; Bernstein 2008). The EACDS-based scheme utilized a difference set scaled by another difference

set, which is called the exponential set. The scaling was done by the Kronecker product and guaranteed that there was at least one overlapping slot between any two EACDSs with different duty cycles. For example, a difference set (v_I, k_I, λ_I) , called an initial set, is scaled by another difference set (v_E, k_E, λ_E) , called an exponential set. Then, the higher level hierarchical set can be obtained by the Kronecker product, i.e., $(v_I, k_I, \lambda_I) \otimes (v_E, k_E, \lambda_E)$, where operator $\otimes$ denotes the Kronecker product. The MACDS-based scheme used a multiplier set instead of the exponential set. All multiplier sets were selected from the relaxed difference sets (Luk and Wong 1997). The performance evaluation revealed that the MACDS-based scheme conserves more energy, whereas the EACDS is more suitable for scenarios where many different duty cycles are required.

Another extension of CDS-based protocol is to utilize permutation and combination to generate a longer cycle period for each sensor node (Su et al. 2016). Based on the Singer difference set, there exist $q + 1$ $\binom{q}{q+1}$ possible position combinations for q active slots in one subcycle. For example, when $q = 2$, we get a (7,3,1)–cyclic different set: $D = \{1,2,4\}$. There are three possible position combinations which has two active slots in one subcycle, and they are $\{1,2\}$, $\{1,4\}$, and $\{2,4\}$, as shown in Fig. 4.

One full operating cycle of a sensor node contains concatenation of all possible subcycles, each corresponding to a distinct position combination of any q active slots. Therefore, an operating cycle is comprised of $(q + 1)$ subcycles, which corresponds to $(q + 1) \cdot (q^2 + q + 1)$ slots, $(q + 1) \cdot q$ of which are active slots. Any ordering of subcycles can be used for concatenation. One working cycle period of a sensor node contains $(q + 1) \cdot (q^2 + q + 1)$ active slots. Thus, the duty cycle is $q/(q^2 + q + 1)$. Figure 4 shows an example when $q = 2$.

Table 1 summarizes duty cycles used in Su et al. (2016) and the CDS-based protocol (Zheng et al. 2003). For a given value of q , the proposed scheme in Su et al. (2016) can generate a smaller duty cycle than the CDS-based protocol. It is obvious that a larger value of q can achieve a

Asynchronous Coordination Techniques, Fig. 4 Extension of the CDS-based protocol by permutation and combination

Asynchronous Coordination Techniques, Table 1 Duty cycles used in Su et al. (2016) and the CDS-based protocol (Zheng et al. 2003)

q	Duty cycles (%) (Su et al. 2016)	Duty cycles (%) (Zheng et al. 2003)
2	28.57	42.85
3	23.08	30.77
4	19.05	23.81
5	16.13	19.35
7	12.28	14.04
8	10.96	12.33
9	9.89	10.99
11	8.27	9.02

smaller duty cycle and thus reduce more energy consumption for idle listening. However, normally, for a given smaller duty cycle, a sensor node requires more active slots to connect to a next-hop sensor node.

Tables 2 and 3 compare the proposed scheme in Su et al. (2016) that is extended using Kronecker product to the EACDS and MACDS proposed in Choi and Shen (2011), respectively. For EACDS, $(v_E, k_E, \lambda_E) = (3, 2, 1)$. For MACDS, (v_M, k_M, λ_M) is selected from the rotational set group as used in Luk and Wong (1997). For the scheme proposed in Su et al. (2016) and the EACDS and MACDS, $q = 2$ is chosen as an example. From Tables 2 and 3, for given values of q, n , and (v_M, k_M, λ_M) , the smaller duty cycles can be generated by the scheme proposed in Su et al. (2016) using the Kronecker product rather than EACDS and MACDS.

Heterogenous CDS-Based Schemes

The length of a cycle period and the corresponding number of active slots determines the energy

(24,6,1)	7.14	10.71
(48,8,1)	4.76	7.14

consumption of underwater sensor nodes when data exchanges do not frequently occur in long-term monitoring applications. When some nodes need to change the cycle length dynamically to satisfy the requirements of energy and packet delay and the other sensor nodes keep unchanged, the network connectivity will be lost when the wake-up coordination scheme do not guarantee that any two sensor nodes can communicate at least once in one cycle period. The heterogeneous CDS-based schemes can keep the network connectivity when different CDS-based wake-up

coordination schemes are adopted by different sensor nodes.

Cyclic quorum system pair (CQS-pair) is a heterogenous asynchronous wake-up coordination scheme based on the CDS-based protocol, which is derived by using the Singer cyclic difference set (Theorem 1) and the multiplier theorem (Theorem 2) (Lai et al. 2010). Moreover, a verification matrix is used to verify that any two heterogenous difference sets have the rotation closure property. To be more specific, sensor node a adopts a difference set $\{a_1, a_2, a_3, \dots, a_k\}$ in $(Z_N, +)$ and sensor node b adopts another difference set $\{b_1, b_2, b_3, \dots, b_l\}$ in $(Z_M, +)$, where $N \leq M$ and $p = \lceil M/N \rceil$. The proposed verification matrix (Lai et al. 2010) is defined as a $pk \times l$ matrix $M_{l \times pk}$ whose element $m_{i,j}$ in the matrix is calculated by $(b_i - a_j^p) \pmod{M}$ and $a_j^p \in A^p$, as presented as follows.

$$M_{l \times pk} = \begin{bmatrix} b_1 - a_1^p & \cdots & b_1 - a_{pk}^p \\ \vdots & b_i - a_j^p & \vdots \\ b_l - a_1^p & \cdots & b_l - a_{pk}^p \end{bmatrix} \quad (3)$$

Sensor node a and b have the rotation closure property if $M_{l \times pk}$ contains all elements from 0 to $M - 1$, which means these two heterogeneous difference sets can keep network connectivity when sensor nodes utilize them respectively.

For example, according to Theorems 1 and 2, there are two (7,3,1)-cyclic difference sets: $\{1,2,4\}$ and $\{3,5,6\}$ in $(Z_7, +)$ when a cycle period contains 7 slots. Similarly, there are two (21,5,1)-cyclic difference sets: $\{3,6,7,12,14\}$ and $\{7,9,14,15,18\}$ in $(Z_{21}, +)$ when a cycle period contains 21 slots. By using Eq. (3), sensor nodes can switch between a (7,3,1)-cyclic difference set with $\{1,2,4\}$ and a (21,5,1)-cyclic difference set with $\{7,9,14,15,18\}$ without sacrificing the network connectivity. Another pair of wake-up coordination schemes is a (7,3,1)-cyclic difference set with $\{3,5,6\}$ and a (21,5,1)-cyclic difference set with $\{3,6,7,12,14\}$. Unlike the proposed schemes in Chao et al. (2006), Zheng et al. (2003), Choi and Shen (2011), and Su et al. (2016), the CQS-pair (Lai et al. 2010) provides more choices

for sensor nodes to adapt dynamic changes of network requirements without further improving the energy consumption for long-term monitoring applications.

Key Applications

Asynchronous wake-up coordination scheme has been involved in different scenarios, such as long-term marine environmental monitoring, undersea resource explorations, assisted location and navigation, delay-tolerant data transmission, and some energy-limited applications. With the development of internet of underwater things (IoUT), the communications among multiple underwater autonomous vehicles (AUV) and the cooperation between AUV and glider can utilize asynchronous wake-up coordination scheme to prolong the network lifetime and extend the monitoring area.

Future Directions

Asynchronous wake-up coordination scheme brings energy efficiency for UWSNs. However, it also prolongs the data packet delay compared with on-demand and synchronous wake-up coordination schemes. Some challenges are presented below.

- Balancing between energy consumption and packet delay

It is obvious that the longer cycle period leads to low duty cycles for sensor nodes so as to significantly improve the energy efficiency. However, the packet delay is prolonged because not all sensor nodes are always active and the neighboring nodes discovery requires more time (or time slots) with a low duty cycle. Consequently, to achieve a balance between packet delay and energy consumption is a challenge for UWSNs when considering the nontrivial propagation delay by adopting asynchronous wake-up coordination scheme. On the other aspect, according to the data traffic or historic connection information (e.g., which active slots always enable the

communication connection), how to select a proper duty cycle (i.e., network operation pattern such as (7,3,1)–cyclic difference set-sets: {1,2,4}) achieves a balance between energy consumption and packet delay, which can be further investigated.

- Mobility of sensor nodes

In traditional UWSNs, all sensor nodes are supposed to be fixed on the seafloor in UWSNs. In the internet of underwater things (IoUT), AUVs serve as mobile sensor nodes, which can gather data in a large area for long-term monitoring applications. Directly utilizing aforementioned asynchronous wake-up coordination schemes may lead to non-trivial energy consumption and packet delay caused by the neighboring node discovery when a mobile sensor node is out of communication range of its intended nodes. How to adjust the asynchronous wake-up coordination scheme to accommodate the varying network topology in an energy-efficient manner is still an open issue in this area.

Definitions

Auction is a concept from microeconomics, referring to the practice of buying and selling goods through the process of bidding. Auction participants include buyers, sellers, and the auctioneer, and the role of the auctioneer may be assumed by

the seller, especially if there is a single seller. An auction mechanism is a series of rules specifying how an auction is conducted. The three most important components of an auction mechanism are the determination of the winners, the allocation of items, and the payment.

Historical Background

Auction is deemed as an effective way to assign items to buyers who value them the most. According to different numbers of participants, auctions can be categorized into three settings.

- *Forward auction*. One seller, who also acts as the auctioneer, and multiple buyers.
- *Reverse auction*. One buyer, who also acts as the auctioneer, and multiple sellers.
- *Double auction*. Multiple buyers, multiple sellers, and a third-party auctioneer.

In the forward auction, if there is a single piece of item, there are four standard auction mechanisms.

- *English auctions* or open ascending-bid auctions. Buyers openly bid against each other by iteratively raising their bids to be higher than the current highest bid. The auction terminates when no buyer offers a higher bid, and the buyer with the highest bid wins the item and pays the corresponding price.
- *Dutch auctions* or open descending-bid auctions. The auctioneer starts with a high bid and then lowers the bid until some buyer accepts and pays the corresponding price.
- *First-price sealed-bid auctions*. Buyers bid simultaneously without knowing each other's bids, i.e., sealed bids. The buyer with the highest bid wins the item and pays the corresponding price. Different from the English auction, buyers can only submit their bids once and cannot adjust the bids according to other buyer's bids.

- *Second-price sealed-bid auctions.* This type of auction is identical to the first-price sealed-bid auctions, with the exception that the winner pays the second-highest bid.

These four types of auctions can be easily extended to reverse auctions and to accommodate multiunit items, and there have been many variants and extensions of these standard auction mechanisms. Besides, there are several other more advanced auction mechanisms.

- *Combinatorial auctions.* Combinatorial auctions allow buyers to bid on combinations of items, such that the bid on a combination may not equal the sum of bids on individual items in the combination. For example, a buyer bids \$1 on item A and \$2 on item B , but may bid \$2.5 on the combination $\{A, B\}$ if A and B are substitutes, or bid \$4 on the combination $\{A, B\}$ if A and B are complements to each other.
- *All-pay auctions.* Normally, nonwinning buyers or sellers will not pay in auctions. All-pay auctions exert a compulsory payment on every participant and may be used to model entry fees or other costs in the process of auctions.
- *VCG auctions* (Vickrey 1961; Clarke 1971; Groves 1973). Vickrey-Clarke-Groves (VCG) auction mechanism tries to maximize social welfare with feasible allocations that satisfy the constraints of the auction (e.g., total number of auctioned items). Take forward auction as an example. The auctioneer finds one optimal feasible allocation A^* that maximizes the total bids of all winning buyers (usually through brute force). The payment of a winning buyer i with bid b_i is calculated as follows. The auctioneer removes buyer i and finds the optimal feasible allocation $\tilde{A}^*$ among the rest of the buyers. Then, buyer i will be charged the price of $\sum_{j \neq i} b_j(\tilde{A}^*) - \sum_{j \neq i} b_j(A^*)$, i.e., the difference of the utility of other buyers when buyer i participates in the auction or not. The VCG mechanism can achieve truthfulness and social welfare maximization, but its major drawback is high computational complexity, since it is often NP-hard to find the optimal feasible allocation.
- *McAfee auctions* (McAfee 1992). The McAfee auction mechanism is developed for single-unit or multiunit double auctions. Take the single-unit auction, for instance. Based on their bids, the auctioneer sorts the sellers in a non-descending order and the buyers in a non-ascending order. The auctioneer finds k , the last profitable pair of seller and buyer, i.e., the bid of the k -th buyer is higher than that of the k -th seller, but the bid of the $(k + 1)$ -th buyer is lower than that of the $(k + 1)$ -th seller. The first $(k - 1)$ sellers win, and each receives the payment of the bid of the k -th seller; the first $(k - 1)$ buyer win and each pays the bid of the k -th buyer.

Since auction participants are selfish and rational individuals who will adopt the optimal bidding strategy to gain the highest utility, game theory can be applied to analyze auctions. An auction is economic robust if the following three properties are satisfied.

- *Individual rationality.* A buyer or a seller is individually rational in the sense that they will not participate in the auction if the obtained utility is less than the utility of no participation. An auction mechanism is individually rational, if all sellers and buyers achieve non-negative utility. This usually means that any seller is paid more than its bid, and any buyer pays less than its bid.
- *Truthfulness or strategy-proofness.* The buyers and sellers have the motivation to manipulate their bids to maximize their own utilities. Being truthful means that a seller or a buyer will submit a bid that equals their true valuation for the item. A truthful auction mechanism guarantees that a buyer or a seller cannot get a higher payoff by misreporting their true valuations; thus they will have no incentive to be untruthful.
- *Budget balance.* Budget balance is often considered in the double auction. It means that the auctioneer maintains nonnegative budget. In

other words, the payment that the auctioneer receives from all buyers is no less than the payment given to all sellers. For regulators, budget balance is often enough to motivate them to host spectrum auctions. The profit-oriented auctioneers, however, may aim at revenue maximization.

Apart from economic robustness, there are several other concerns in the design of auction mechanisms.

- *Social welfare.* Generally speaking, social welfare is the utility of all auction participants, including the buyers, the sellers, and the auctioneer. As the payment merely transfers utility among auction participants, it does not contribute to the social welfare. Therefore, the social welfare can be calculated as the difference between the total true valuation of winning buyers and the total true valuation of winning sellers. In a truthful auction, the social welfare is simply the total bid of winning buyers minus the total bid of winning sellers.
- *Collusions.* Auction participants may collude to rig the auction and gain a higher utility. For example, buyers may form collusions to bid against other buyers but not the buyers in the collusion, resulting in a favorable allocation and a lower payment. The seller may collude with the auctioneer to insert dummy bids to gain a higher payment. The practice of collusion in auctions has been revealed by many empirical studies, calling for effective countermeasures.
- *Privacy-preserving.* The bid of a buyer may be sensitive and private information that should be shielded from the non-trustworthy auctioneer and other rival bidders. For example, in a truthful auction, a buyer's bid is its true valuation, which may be closely related to its profit of winning the spectrum. The disclosure of sensitive information will render unbalanced advantage to the informed entities and cause economic damage to those whose information is divulged. Therefore, privacy-

preserving auction mechanism design is gaining more and more attention.

Key Applications

The most successful application of auctions in wireless networks is dynamic spectrum allocation. Spectrum is an indispensable resource for wireless communications. To address the underutilization problem resulted from static spectrum allocation, it is proposed to dynamically redistribute spectrum through auctions. Different from traditional goods, spectrum features interference-constrained spatial reuse, i.e., the same channel can be reused by multiple non-interfering buyers whose transmission ranges do not overlap. Therefore, the objective of spectrum auctions is to realize spectrum reusability while achieving economic robustness or social welfare maximization. The interference relationship of buyers is usually represented by the interference graph, an undirected graph constructed based on the transmission range of the spectrum and geographic information of the buyers. A typical interference graph can be denoted as $G = (V, E)$, in which the set of nodes V represents the set of buyers and the set of edges E represents interference relationship. If two buyers interfere with each other, there is an edge between them; otherwise, there is no edge between them.

The following are some typical spectrum auction mechanisms.

- *Forward spectrum auction* (Zhou et al. 2008; Jia et al. 2009). The single spectrum owner with M channels acts as the auctioneer, and each buyer can demand more than one channels. After sorting the buyers according to their bids in a non-ascending order, the auctioneer will sequentially check each buyer. If the buyer's demand d_i is fewer than the available channels $M - e_i$, in which e_i is the number of channels allocated to the buyer's interfering neighbors, the buyer will become a winner. A winning buyer will pay according to the critical value, which is the lowest value that the buyer has to bid in order to win.

- *Double spectrum auction* (Zhou and Zheng 2009). Assume that each buyer demands one channel and each seller owns one channel. The third-party auctioneer first divides buyers into groups, each of which only contains non-interfering buyers. The group bid is determined by the group size and the minimum bid in the group. Regarding each buyer group as a virtual buyer, the auctioneer can execute the McAfee auction mechanism to determine the spectrum allocation and the payment.
- *Heterogeneous spectrum auction* (Feng et al. 2012; Chen et al. 2014). The difference between homogeneous and heterogeneous spectrum auctions is that heterogeneous spectrum auction groups non-interfering buyers on a per-channel basis, since the interference relationship of buyers on different channels is different.
- *Combinatorial spectrum auction* (Zheng et al. 2015). Motivated by the fact that channels of contiguous frequency are easier to operate, combinatorial spectrum auction allows buyers to bid on combinations of channels. To realize spatial reuse, the same channel in the combinations of two non-interfering buyers is represented by two different virtual channels. Then, buyers are sorted in the non-ascending order according to the ratio of the bid to the combination size. The auctioneer then sequentially checks each buyer and selects winners as those whose demanded combination does not contain any channel that has already been allocated. A winning buyer will also pay its critical value, as in the forward spectrum auction.
- *Online spectrum auction* (Wang et al. 2010). Online spectrum auctions involve the temporal dynamics of spectrum demand and supply and require buyers to specify their requested time slots. At each time slot, the auctioneer collects bids from the arriving buyers and examines the availability of channels. Given the current buyers, the auctioneer will first conduct a screening process to remove the buyers whose bids are lower than the estimated future value of the channel. Then, the auctioneer can determine spectrum allocation

among the remaining buyers using the double spectrum auction mechanism.

Apart from spectrum distribution, auction has been applied to other scenarios in wireless networks.

- *Power allocation*. Auctions can enable wireless users to cooperate in distributed power allocation to improve the overall network performance (Liu et al. 2013).
- *Crowdsensing*. Mobile crowdsensing platforms can adopt auctions to incentivize the participation and high-quality works from crowd workers (Luo et al. 2017).
- *Mobile data offloading*. Wireless service providers can use auctions to employ Wi-Fi or femtocell access points for data offloading (Iosifidis et al. 2015).
- *Video streaming*. Auctions can be used to motivate nearby wireless users to cooperate in video downloading and sharing, thus improving wireless video streaming performance (Han et al. 2009).

[IEEE 802.11](#); [IEEE 802.1x](#); [Wireless credentials](#); [WLAN authentication](#)

Definitions

Authentication methods in wireless networks allow the wireless access point (AP) or broadband wireless router to authorize individuals and devices, and only those who get authorized can access the network. For maximum security, client devices should also authenticate to the wireless network using pre-shared key (PSK) or Extensible Authentication Protocol (EAP) authentication. The use of mutual authentication is essential in a wireless network. This will guard against many security issues, such as man-in-the-middle (MITM) attacks. With authentication, the wireless client and the wireless AP must prove their identity to each other.

Historical Background

When setting up a wireless network, the network administrator has to have some way to ensure that wireless clients, and the devices they are using, are trusted. A typical solution to this question is to use a standard kind of authentication, which in today's wireless network area means IEEE 802.11 and 802.1x authentication.

The first wireless network standard, 802.11, permits a network to be made relatively secure if the user establishes their wireless network using the Wired Equivalent Privacy (WEP) protocol (IEEE 1999). Since the data is transmitted over the air, it is a simple task for a malicious device to sniff it and grab sensitive information. To avoid this type of attack, WEP consists of a

passphrase that uses secret and shared encryption keys that are generated by the wireless host and then passed to the wireless client. These keys are used for encrypting all the data that travels across the airwave and thus thwarting anyone trying to sniff the network. In WEP, there are two authentication mechanisms: (1) open system authentication (OSA) and (2) pre-shared key authentication (PSK). However, it is well known that the IEEE 802.11 WEP protocol is vulnerable to two types of attacks: (1) message privacy and message integrity attacks (Johnson and Maltz 1996) and (2) probabilistic cipher key recovery attacks, such as the Fluhrer-Mantin-Shamir attack (Fluhrer et al. 2001; Stubblefield et al. 2002). In 2003, the Wi-Fi Alliance announced that WEP had been superseded by Wi-Fi Protected Access (WPA) protocol. WPA protocol has the addition of the Temporal Key Integrity Protocol (TKIP). TKIP avoids the problems of WEP by implementing per-packet key mixing with a rekeying system and message integrity check (MIC) mechanism. In 2004, as an updated version of WPA, WPA2 was released along with the IEEE 802.11i standard. Both WPA and WPA2 support the PSK authentication key distribution mechanism and use a stronger encryption than WEP. It is designed for home and small office networks and doesn't require an authentication server.

Another wireless network standard, the IEEE 802.1x, is widely adopted for large wireless area networks such as a hotel or big company. It takes the predecessor IEEE 802.11 one step further and includes computer and user identification, dynamic key creation, and centralized authentication. IEEE 802.1x supports the Internet Authentication Service (IAS) which uses the Remote Authentication Dial-In Service (RADIUS) protocol. In addition, 802.1x ties to the Extensible Authentication Protocol (EAP) which supports multiple authentication methods such as Kerberos, public key authentication, and certificates.

Many security issues have been found in these wireless authentication protocols. In 2008, an attack on TKIP (Beck and Tews 2009) was released which allows an adversary exploiting WPA's MIC. In 2017, security researchers have discovered a significant vulnerability, named

KRACKs (Vanhoeft and Piessens 2017), in WPA2. It uses a group of vulnerabilities that exist in the implementation of the authentication protocol to launch key reinstallation attack and eventually allows the attacker to intercept and steal data. In January 2018, Wi-Fi Alliance announced the release of WPA3 with several security improvements over WPA2.

Foundations

There are three main methods of authentication that are used on wireless networks.

- **Open System Authentication:** Open system authentication allows any wireless device to connect to the network as long as the end device knows the service set identifier (SSID) used on the network. The significant advantage of this type of authentication is its simplicity: any client can directly connect without complicated configuration. The problem with this authentication scheme is that the SSID is typically broadcast so any device within the wireless coverage range can join the network. Moreover, the SSID can be obtained from the association request frames even if the access point is set not to broadcast the SSID.
- **Pre-Shared Key Authentication:** The pre-shared key authentication method is commonly used on individual and small business wireless networks. It uses a pre-shared key that is distributed to the client device before establishing the connection. The PSK allows any wireless client who has the key to join the network. The client also has the option to use the key to encrypt the data. This can protect sensitive data traveling across the wireless network from becoming captured. The original 802.11 WEP protocol utilizes RC4 for encryption and has been deprecated due to several vulnerabilities. The improved WPA protocol ties with the TKIP which utilizes dynamic keys that were not supported with WEP for encryption. However, a similar vulnerability has been found since TKIP uses the same procedures that WEP does. WPA2

replaced TKIP with Counter Mode Cipher Block Chaining Message Authentication Code Protocol (CCMP) which is primarily based on Advanced Encryption Standard (AES), and it is proven to provide strong encryption.

A PSK is relatively easy to configure though it requires some configuration at the client side. However, a wireless network based on a PSK does not scale well. With a large number of clients, it becomes more difficult to periodically update the PSK.

- **EAP (Extensible Authentication Protocol) Authentication:** EAP authentication is an arbitrary authentication mechanism that is used in the wireless network, and it is part of the 802.1x standard. EAP allows for several choices of authentication methods including MD5, EAP-TLS, EAP-TTLS, and PEAP. In order to use EAP to authenticate users when they connect to the wireless network, a third-party authentication server is required at time of the client association, such as RADIUS. The wireless host opens the client's port for other types of traffic based on access rights stored in the authentication server.

Key Applications

Authentication is one of the most important parts of wireless protocol which is used for establishing user identities and for securing the wireless communication.

[Automotive cybersecurity](#); [In-vehicle security](#); [Vehicle cybersecurity](#)

Definitions

Automotive Security is the field of assessing cyber-threats against automotive systems and developing security countermeasures for detecting, preventing the corresponding attacks, and reacting to a security breach. As modern vehicles become connected, the threat of attack becomes increasingly real. Coupled with advances in driver assistance and autonomous solutions, the impact on security is further expanded. Thus, automotive security aims at ensuring automotive systems can achieve their intended function without the danger of being maliciously manipulated by an attacker. A few definitions used in vehicle security are provided below:

- **Cyber-physical system:** A system of collaborating computational elements controlling physical entities
- **Cybersecurity:** An attribute of a cyber-physical system that relates to avoiding unreasonable risk due to an attack (Committee SVESS et al. 2016)
- **Attack:** Exploitation of vulnerabilities to obtain unauthorized access to or control of assets with the intent to cause harm
- **Threat:** A circumstance or event with potential to cause harm
- **Exploit:** An action who uses vulnerability to cause undesired, unexpected, or unanticipated behavior
- **CAN:** Control Area Network is a dominant communication network protocol used for intra-vehicle communication

Historical Background

Automotive security related threats initially came to light with the introduction of keyless entry systems. For such vehicles, the primary threat was that of theft, and vehicle manufacturers were keen on implementing security features to prevent a thief from wirelessly unlocking the vehicle and driving off (Biham et al. 2007). Security features included rolling codes as well

as immobilizer units that can prevent the vehicle from starting unless the correct key is present. Another area that initially gained recognition was the tire pressure monitoring sensors (TPMS) (Heary 2010). These sensors gave off RF signals that could be used to allow tracking of vehicles, which would violate the driver's privacy. As vehicles added more connectivity features through a telematics unit, USB devices, bluetooth, and Wi-Fi, the attack vectors increased drastically and so did the interest of the research community to uncover potential exploits that could be found in these systems. The work of Checkoway et al. (2011) was instrumental in showing the extent to which attacks could be launched against vehicles through various attack surfaces like OBD tools, CD Roms, and more. This brought cybersecurity to the forefront in the minds of vehicle OEMs who knew that security needed more attention. The attacks by Miller and Valasek (2015) launched remotely on the Jeep in 2015 further demonstrated that the threats were not only academic but real, and lead FCA to ship USB sticks with patches to close the security vulnerabilities uncovered by the attacks. Even before that date, several standardization bodies were aware of the need to address cyber threats on vehicle systems. One of the early ones was EVITA, a European Commission tasked with defining security use cases and deriving security requirements for vehicle systems. EVITA produced 18 use cases and defined a security architecture for on-board automotive networks as well as a threat assessment method.

In addition to EVITA, several other industry initiatives were created to address automotive security. Some of these are provided below:

- **SAE J3061:** The first cyber-security framework to address all the main security aspects of producing secure automotive systems (Committee SVESS et al. 2016).
- **C2C:** Car to Car communication consortium aims to create a European industrial standard for communicating cars.
- **ETSI C-ITS:** A not-for-profit organization aims to achieve standards for Cooperative Intelligent Transport Systems.

- USDOT/CAMP: A joint initiative to produce a security credential management system (SCMS).
- AUTOSAR WP-X: The security working group within AUTOSAR produces software specifications to define security functions in embedded systems.
- UPTANE: An academic and industry co-initiative to standardize Over-the-Air updates in vehicles.
- AUTO-ISAC: An industry and government co-initiative for information sharing across the automotive supply chain relating to cyber threats (Auto ISAC 2017).
- ISO and SAE joint working group to produce a common cyber security standard: ISO-SAE 21434.
- IEEE Standard for Wireless Access in Vehicular Environments (IEEE 1609.2).

Foundations

To study automotive security, one usually starts with threat analysis and risk assessment to identify attack surfaces, attack agents, security objectives, and controls.

Threat Analysis and Risk Assessment processes: In a fashion that parallels the hazard and risk assessment of functional safety (ISO 2011), automotive security requires the enumeration of threats and the qualification of the corresponding risk. There exist several threat assessment methods such as EVITA-THROP (Henniger et al. 2009), OCTAVE (Alberts et al. 2003), TVRA (IMS 2008), HEAVENS (Islam et al. 2014), and NHTSA composite modeling (McCarthy et al. 2014). Once the threats are identified and the corresponding risk is calculated, product developers derive security requirements to address the associated threats. The higher the risk of an attack and its impact, the more stringent the security level would be, which means added hardware countermeasures, and a stricter security profile.

Attack Surfaces: With added connectivity comes the risk of added exposure to security threats due to the ever expanding attack surface. As shown in Fig. 1, today's vehicles offer

numerous attack surfaces. In order to address these cyberthreats, automotive security engineers create security defenses both at the vehicle boundary and at the internal vehicle layers. Figure 1 provides an overview of vehicle communication interfaces. Dotted lines represent wireless connections, while solid lines represent wired connections.

Attack Agents: An important element in automotive security is the agent who is performing the attack. Different agents will have different capabilities, resources, expertise and motivations. For example, a mechanic has far less capabilities and different attack motivations from a nation state hacker. The following is a list of different attack agents who might compromise a vehicle.

Threat Agent

- Thief
- Vehicle Owner
- Mechanic
- Hacktivist
- Organized Crime
- Researcher
- Terrorist
- State sponsored

Security Objectives: Automotive security is different from IT security due to the dimension of control which results in security threats impacting safety. Still, several security objectives are typical of IT systems with the exception that the assets being protected are automotive specific. Among the primary security objectives for automotive systems are:

- Prevent attacks that have an impact on vehicle safety
- Protect driver privacy and prevent vehicle tracking
- Protect vehicle OEM reputation and brand
- Protect algorithms and IP especially ones related to Autonomous and ADAS systems, from theft through reverse engineering

Throughout the automotive industry, there is a general consensus that automotive security

Automotive Security,
Fig. 1 Attack surfaces

A

requires a security-in-depth approach. This translates to providing security at each layer of a vehicle interface (known as the layered approach). The first layer being the vehicle external interface (telematics unit, OBD, infotainment, etc.). The second layer being the vehicle network gateway that separates different vehicle domains and allows for filtering network data inside the vehicle. The third layer being the vehicle network within each domain. And the fourth layer being the Electronic Control Unit itself, primarily the microcontroller unit, sensors, and the software that goes along with it. Building defenses at each one of these layers is meant to increase the attack difficulty to a point that discourages an attacker from attempting to compromise a vehicle system, as the payoff would not justify the required effort.

Security Primitives and Key Applications

To ensure automotive security, researchers in the industry and academia have come up with a range of security requirements that apply to automotive ECUs:

- **Secure Debug:** Accessing to JTAG as well as any debug interface shall be locked to prevent reverse engineering and theft of vehicle IP.
- **Secure Diagnostics:** Vehicles contain extensive diagnostic services meant to allow the OEM to fully diagnose an ECU failure to aid in vehicle maintenance as well as test for

emissions. Such diagnostics shall be protected against attackers who can use these services to manipulate the vehicle.

- **Secure Programming:** Automotive ECUs rely on flash bootloaders to update vehicle software. All application and calibration data shall be cryptographically signed to prevent an attacker from modifying the vehicle software.
- **Secure Communication:** Automotive systems are highly reliant on CAN as the primary network protocol. Since CAN has no built-in security features, it is important to define security protocols that can prevent an attacker from spoofing control or status messages on the CAN bus.
- **Secure Boot:** Checking the authenticity of vehicle software after each boot cycle provides added assurance that vehicle software was not tampered with while at rest.

The above security requirements apply to a variety of automotive ECUs. The below list highlights specific security application areas:

- **Telematics:** Provide various forms of connectivity such as cellular and Wi-Fi. Therefore, they open the door to remote-based attacks. Such systems require strong firewalls to block unwanted traffic into the vehicle.
- **Infotainment:** Such systems are primarily used to provide audio/video and navigation to the end user. By their nature, they use rich operating systems like Android and Linux. To isolate such applications from critical vehicle systems, sandboxing and trustzones are important

to provide isolation between the trusted and untrusted world.

- V2X: Vehicle-to-Everything is another emerging set of communication protocols. Such systems have special requirements for processing a large number of ECC calculations to authenticate other entities. Due to the high potential impact to safety, the hardware in such systems is expected to support FIPS 140-2 level 3 or higher HSMs.
- Vehicle Gateway: Network domains separate vehicle functions into separate CAN bus systems. In this scenario, methodologies such as network isolation and intrusion detection systems are used to detect and prevent outside and inside intruders (Kaja et al. 2017; Zhang et al. 2018).
- In-Vehicle Network: In-Vehicle networks enable ECU-to-ECU communication via robust and reliable networks. In order to secure such networks, different mechanisms are used such as AUTOSAR SecOC, for authentication, and Freshness.
- Sensors: The number of sensors in a vehicle has ballooned to allow understanding of its surrounding. Authenticating sensor data and source is important to prevent sensor spoofing or sensor counterfeiting.
- AUTOSAR based ECUs: As one of the most widely prevalent automotive software platform, AUTOSAR now presents a rich area of study in automotive embedded security. Therefore, applying best practices within AUTOSAR for increasing the security resilience of such systems is mandatory (Nasser et al. 2017)

Bandwidth Allocation in Data Center Networks

Haojun Yang and Kan Zheng
Intelligent Computing and Communications (IC²) Lab, Wireless Signal Processing and Networks (WSPN) Lab, Key Laboratory of Universal Wireless Communications, Ministry of Education, Beijing University of Posts and Telecommunications (BUPT), Beijing, China

Synonyms

[Resource allocation](#)

Definition

In data center networks (DCNs), infrastructure as a service (IaaS) providers can flexibly allocate bandwidth in order to achieve diverse benefits for providers and tenants. For the IaaS providers, appropriate schemes of bandwidth allocation can improve the utilization of DCNs, and thus more revenues can be generated. On the other hand, the amount of bandwidth allocated for the tenants largely determines the performance of applications and the fairness of coexisting tenants.

Historical Background

In recent years, cloud computing is widely developed for providing various Internet services such as search, video caching, and distributed storage. To efficiently meet the requirements of data-intensive cloud computing applications, large-scale DCNs are built by IaaS providers. Among diverse studies of DCNs, bandwidth allocation plays a key role; it has been investigated from different perspectives, achieving many advances (Bari et al. 2013; Del Piccolo et al. 2016; Xia et al. 2017; Zhang et al. 2018).

As the most common and simple scheme, the best effort manner of bandwidth allocation is first introduced. In general, the best effort allocation cannot satisfy the explicit demands specified by tenants. As a result, malicious tenants can unfairly improve the network performance by establishing multiple Transmission Control Protocol (TCP) connections or simply using User Datagram Protocol (UDP) (Xia et al. 2017), which leads to the bandwidth guarantee of normal tenants not being ensured. To this end, fairness is the future research focus in the best effort sharing.

In contrast to the best effort sharing, static bandwidth reservation scheme can provide bandwidth guarantee for each tenant according to its requirement (Chen et al. 2014) and thus is

widely studied recently. The obvious advantage of deterministic allocation is that the bandwidth available to a tenant is irrespective of the network traffic from other tenants. However, when tenants do not fully make use of their bandwidth, static bandwidth reservation scheme will lead to the low utilization of DCNs. Therefore, improving the utilization is crucial issue in bandwidth guarantee-like schemes.

Foundations

Requirements of Bandwidth Allocation

Bandwidth allocation in the DCNs generally depends on many aspects including guarantee, fairness, and utilization (Sun et al. 2016; Chen et al. 2014).

Guarantee is an important requirement affecting the performance of DCNs. The static scheme mentioned above can provide perfect performance isolation among all the tenants. Therefore, it is also referred to as full bandwidth guarantee. In order to further improve the utilization of full bandwidth scheme, a flexible method is minimum bandwidth guarantee, which enables tenants to achieve worst-case performance and thus to bound costs.

When guarantee cannot be ensured, fairness will be the crucial requirement in bandwidth allocation. In public clouds, fairness allocation means that bandwidth is divided in proportion to the payments among all tenants. While in private clouds, the abovementioned definition of fairness is no longer applicable. Specifically, fairness generally depends on the performance of different applications, i.e., the priority and quality of service should be considered.

It is vital to fully utilize the available bandwidth in DCNs. Intuitively, achieving high utilization is to find the optimal bandwidth allocation by various traffic control methods. The idle bandwidth should be used for meeting application demands as far as possible in private clouds. With regard to public clouds, IaaS providers should establish encouragement

mechanisms for tenants to improve the utilization of bandwidth.

Solutions of Bandwidth Allocation

Minimum Guarantee Bandwidth Allocation

Minimum bandwidth guarantee can provide the bandwidth specified in a service-level agreement, achieving the worst-case performance. Two representative static bandwidth reservation solutions are first introduced, i.e., SecondNet and Oktopus can ensure per-flow and per-tenant bandwidth guarantee, respectively (Guo et al. 2010; Ballani et al. 2011).

However, maintaining a fixed bandwidth is not always practical in the real world. Therefore, based on the time-varying requirements, Proteus proposes a virtual network abstraction model called time-interleaved virtual clusters (Xie et al. 2012). The bandwidth demand on each virtual link is described as a time-varying function. Compared with the static reservation solutions, Proteus can significantly improve the utilization of DCNs and reduce the costs on bandwidth.

Jeyakumar et al. put forward the EyeQ solution which provides predictable minimum bandwidth by rate control at senders according to the feedback from receivers (Jeyakumar et al. 2012, 2013). Moreover, Jeyakumar et al. build a test bed to evaluate the EyeQ performance. Another feature of EyeQ is that the rate control is distributed executing at the network edge. Hence, its implementation complexity is relatively low.

ElasticSwitch, also as a distributed solution, ensures bandwidth guarantee under the hose model (Popa et al. 2013). There is two-layer allocation in the ElasticSwitch. First of all, the higher layer transforms the guarantees of virtual machines (VMs) into a set of minimum guarantees for VM pairs. In order to enhance the utilization, the lower layer then dynamically shares the spare bandwidth on a link in proportion to the bandwidth guarantees of VM pairs on the link.

Proportional Bandwidth Allocation

When there are not additional service-level agreements of bandwidth, the bandwidth will be allocated in proportion to what a tenant has paid for other hardware resources, ensuring the allocation fairness in DCNs.

In the NetShare solution, each tenant is assigned with a weight, and the bandwidth is allocated based on the weighted proportionality of all tenants (Lam et al. 2010). The paradigm of the tenant-level fairness can be shifted into the levels of any traffic sources confined to a single tenant, including a VM or a process. Hence, Seawall is proposed in Shieh et al. (2011), where each traffic source is also assigned with a network weight. According to the weights, different traffic sources can acquire the bandwidth proportionally. Furthermore, Seawall adopts a TCP-like congestion control mechanism to limit the transmission rate to obtain per-source fairness.

Another solution is FairCloud proposed in Popa et al. (2012), where the bandwidth allocation is based on the number and weights of VMs owned by a tenant. In general, there are three aspects on bandwidth proportionality, namely, proportional sharing at link-level (PS-L), proportional sharing at network-level (PS-N), and proportional sharing on proximate links (PS-P). In the PS-L strategy, the weight of a tenant on a link is calculated as the sum of the weights of this tenant's VMs which communicate at this link. Similarly with the PS-L, the PS-N policy mainly focuses on the weights of source-destination VM pairs, while the PS-P strategy is generally applied in the tree-based network topology to offer per-source fairness. At last, it is noted that FairCloud is not suitable for deploying in a relatively large scale network, since switches require per-VM queue (Chen et al. 2014).

Key Applications

In various data-intensive cloud computing applications supported by DCNs, bandwidth

allocation of tenants and VMs is the operation fundamental for IaaS providers.

Future Directions

Besides the aforementioned three requirements of bandwidth allocation, we discuss two future research directions including, but not limited to, the following.

1. Timeliness-oriented bandwidth allocation: With the emergence of Internet of things (IoT), diverse latency-sensitive applications are gradually being supported by cloud computing, such as automation control of industrial manufacturing or production processes, autonomous driving and remote medical surgery, etc. Unlike the traditional applications, these types of applications pay more attention to the network performance of latency. Therefore, how to conceive low-latency solutions of bandwidth allocation remains as an open problem for larger-scale DCNs.
2. Energy conservation-oriented bandwidth allocation (Ge et al. 2013): As the scale of future cloud computing is continually expanded, the power consumption of large-scale server rooms will be a thorny issue. Hence, studying efficient energy conservation-oriented bandwidth allocation for DCNs is also one of the future research directions; it can significantly reduce environmental pollution.

Base Station Cooperations Under Imperfect Conditions

Jie Gong

School of Data and Computer Science, Sun Yat-sen University, Guangzhou, China

Synonyms

Coordinated Multipoint (CoMP); Joint precoding/processing; Network MIMO; Virtual MIMO

Definitions

Base station (BS) cooperation is a technique by which multiple BSs simultaneously serve multiple user equipments (UEs) in the same frequency band using networked multiple-input-multiple-output (MIMO) protocol. Figure 1 illustrates a simple example of BS cooperation with two BSs and two UEs. The BSs exchange channel state information (CSI) and UEs' data for cooperation via a central controller. Each BS conveys the desired signals of both UEs as shown by the red and blue arrows, respectively. Different from the conventional MIMO technique, BS cooperation is subject to per-BS power constraints instead of a sum power constraint. Suppose M single-antenna BSs cooperatively serve N single-antenna UEs in the downlink, the system model can be expressed as

$$\mathbf{y} = \mathbf{H}\mathbf{x} + \mathbf{n}, \quad (1)$$

where $\mathbf{y} = [y_1, y_2, \dots, y_N]^T$, y_i is the signal received by the i -th UE, $\mathbf{H} \in \mathcal{C}^{N \times M}$ is the integrated channel matrix between BSs and UEs, $\mathbf{x} = [x_1, x_2, \dots, x_M]^T$, x_i is the signal transmitted by the i -th BS under per-BS power constraint $E[x_i] \leq P_i$, and $\mathbf{n} \in \mathcal{C}^N$ is the noise. In BS cooperation, the signal from each BS can contain all the UEs' data. Hence, the transmitted signal can be expressed as $\mathbf{x} = \mathbf{A}\mathbf{d}$, where $\mathbf{A} \in \mathcal{C}^{M \times N}$ is the joint precoding matrix and $\mathbf{d} = [d_1, d_2, \dots, d_N]^T$, d_i is the desired

B

data of the i -th UE. One of the key issues in BS cooperation is to design the precoding matrix $\mathbf{A}$ under per-BS power constraint $E[x_i] \leq P_i$.

Historical Background

BS cooperation is dedicated to deal with the inter-cell co-channel interference in 4G/LTE networks. Traditional ways of co-channel interference mitigation either require extra bandwidth for large reuse factor or rely on highly complex signal processing which is not practical for mobile devices. With the development of MIMO technologies and the enhanced BS processing capability, BS cooperation has been proposed to deal with the inter-cell co-channel interference. The basic idea is to treat a group of BSs as a “super-BS” with multiple spatially distributed antennas, also known as network MIMO (Karakayali et al. 2006). By sharing UEs’ CSIs and data, multiple BSs coherently coordinate the transmission and reception; thus other-cell signals are used to assist transmission instead of acting as interference. As a consequence, the network capacity can be greatly enhanced. The idea can be originated to distributed antenna systems (Saleh et al. 1987; Zhang and Andrews 2008). Based on this technique, people have proposed a novel architecture called distributed wireless communication sys-

tem (DWCS) (Zhou et al. 2003), where the antennas are distributively deployed and the baseband processors are jointly managed.

Although BS cooperation is expected to significantly improve network capacity, it encounters enormous challenges in practice when considering imperfect conditions. The major categories of the imperfect conditions are summarized as follows:

- *Limited capacity of central controller.* With the increase on the number of cooperating BSs, a central controller needs to handle the joint precoding for the increased number of UEs. To support high-speed data transmissions, high data processing capacity of the central controller is urgently required.
- *Synchronization.* To realize BS cooperation, symbol-level synchronization among BSs should be guaranteed. However, as the BSs are geographically separated, it is very difficult to achieve high-accuracy synchronization. This difficulty may become even more severe when the number of cooperating BSs increases since the variance of the distances to UEs becomes larger.
- *Limited CSI acquisition capability.* The BS cooperation highly depends on UEs’ CSIs for precoding. Therefore, each BS needs to obtain the CSI of all the UEs, which requires a large amount of resources for channel train-

ing and feedback. However, as the feedback channel capacity is limited, the cooperation performance would degrade due to inaccurate channel feedback.

- *Limited backhaul capacity.* The UEs' data needs to be shared among cooperating BSs, which exponentially increases the burden of backhaul link. BS cooperation cannot be fully realized unless there is sufficient backhaul capacity to support UEs' data sharing.

To achieve the expected capacity gain of BS cooperation in real systems, the above imperfect conditions should be taken into consideration. In the next section, candidate solutions are listed with a summary of the state-of-the-art research progress.

Dealing with Imperfect Conditions

The imperfect conditions involved in the real systems induce novel design in cooperative transmission. In particular, the research efforts are classified into the following three parts.

Clustering with Limited Cooperation Size

Due to the limited capacity of the central controller as well as the difficulty in synchronization, it is impossible to form a "super-BS" over the whole network. On the other hand, it is also unnecessary as the cooperation gain with large inter-BS distance is marginal due to the pathloss effect. Consequently, grouping BSs into clusters is a practical and efficient solution. The clustering algorithms can be classified into two categories. The first category is static clustering (Huang et al. 2009), in which the BS cooperation cluster is pre-determined during network planning stage so that it is easy to implement during network operation stage. However, the problem of static clustering is that the cluster-edge UE is severely degraded due to inter-cluster interference. A modified protocol was proposed in Zhang et al. (2009) by suppressing the interference via inter-cluster cooperation. However, the BS cooperation gain will be sacrificed. Thus, people turn to the second

category of clustering, i.e., dynamic clustering according to UEs' channel conditions. A centralized dynamic clustering algorithm was proposed by Papadogiannis et al. (2008b). It is shown that the dynamic clustering with cluster size 2 can perform the same as the static clustering with size 7. Nevertheless, the centralized algorithm requires a large amount of CSIs as well as high computational capacity of the central controller. An improved algorithm was proposed by Liu and Wang (2009) to reduce the cost on channel acquisition. But still, the limited capacity of the central controller is a performance bottleneck.

To further reduce the computational requirement on the central controller, we proposed a distributed dynamic clustering algorithm (Zhou et al. 2009) where the BSs negotiate with each other distributively to form the clusters. The BSs firstly compute the CSI-related weights to represent the potential gain of joining a certain cluster and then exchange the weights to reach an agreement. It is shown that with a small amount of information exchange among the BSs, the proposed distributed algorithm achieves the same sum-rate performance as the centralized algorithm, but the computational complexity and signaling overhead can be greatly reduced. The dynamic clustering algorithm was further extended to overlapping cluster case (Gong et al. 2011), where a single BS can join multiple clusters simultaneously, and hence, the user fairness can be improved compared with non-overlapping clustering methods.

With clustering technique, the practical constraints including limited capacity of the central controller and synchronization issue can be well solved. Firstly, distributed dynamic clustering reduces the capacity requirement on the central controller. The channel training can be launched locally in each BS, the information exchange can be done by the backhaul link, and the clustering decision is made distributively. Secondly, limited cooperation size reduces the difficulty of synchronization. Simulation results show that the dynamic clustering with sizes 2 to 3 can achieve very high sum data rate. The performance improvement by further increasing the cluster size is marginal. Hence in practice,

clustering with sizes 2 to 3 is widely used. In this case, the synchronization is not a difficult task.

Dynamic CSI Acquisition with Limited Feedback

As each BS requires CSIs from all UEs in the same cluster, CSI acquisition should be redesigned for BS cooperation. In TDD mode, by exploiting the uplink-downlink reciprocity, the CSIs of all UEs can be trained via uplink pilot signal. However, the total training slot length is limited. When splitting the training sequence to the UEs, each of them can only be allocated with limited resources and hence has imperfect CSI. In FDD mode, the CSIs can be trained by each UE via broadcasting a training sequence from a BS and then can be fed back to the BS. In this case, each UE needs to feed back the CSIs of multiple cooperating BSs. Due to limited feedback channel capacity, the feedback channel resource allocation should be carefully designed. In the rest of this subsection, we focus on limited feedback in FDD mode.

Limited feedback for a single link or a single cell has been well studied by Love et al. (2008) and the references therein. Different from single-cell case, however, in BS cooperation scenario, there are different pathloss effects between a specific UE and cooperating BSs. Intuitively, the BSs closer to the UE are more valuable for cooperation. As a result, one can ignore CSI from the far BSs and allocate more feedback bits to the near BSs to enhance the overall performance. Papadogiannis et al. (2008a) proposed a threshold-based CSI feedback algorithm to only feed back the CSIs larger than a certain threshold. However, there lack theoretical results on how to determine the threshold. A more dedicated and realistic model is to use quantization and feed back the CSIs by a given number of bits. Quantized CSI feedback was studied by Zhang and Andrews (2010) and Bhagavatula and Heath (2011) for MIMO interference channel, i.e., the CSIs of other UEs are only used for interference suppression. For cooperation, the performance is more sensitive to the CSIs as the precoding matrix strongly depends on the quantized feedback. Based on the above intuition, more bits

should be allocated to strong links, while fewer bits should be used on weak links, so that the influence of feedback error is minimized. This idea was realized by Zhou et al. (2011). In this work, a feedback set of a UE is defined as a subset of BSs to cooperatively serve the UE. Each UE optimizes its feedback set distributively according to the expected signal-to-noise-plus-interference ratio (SNIR) which includes the interference caused by the feedback error. The proposed algorithm outperforms the conventional nonadaptive CSI feedback.

The adaptive quantized CSI feedback deals with the limits on feedback capacity. The basic idea is to utilize the feedback bits on the “most valuable” channels. It is possible that no bits are allocated to some BS as the signal strength is too weak. In this case, the practical cluster size shrinks. Hence, considering the feedback capacity constraint, there is a trade-off between the cooperative gain with large cluster size and the interference caused by the feedback error. Again, the cluster size should not be too large in practice.

Feedback Scheduling with Constrained Backhaul

The backhaul link among BSs is responsible for sharing UEs’ data as well as CSI. When the backhaul link capacity is limited, not all the information can be shared. How to allocate the limited backhaul capacity should be carefully studied. The downlink achievable rate region under backhaul capacity constraint was characterized by Simeone et al. (2009). To fully exploit the advantage of BS cooperation, the idea of superposition coding can be introduced to enhance the ability of sharing data. One way is to share the integrated other-cell signal status, i.e., interference, via interference forwarding (Kim 2008) in the uplink or rate splitting (Maric et al. 2007) in the downlink. The other is to share part of UEs’ data among neighboring BSs for cooperative precoding or interference cancellation (Marsch and Fettweis 2008).

When jointly considering the CSI feedback constraint, the problem becomes more complicated. Both feedback and backhaul

constraints result in imperfect information for cooperation. If the feedback is perfect, the CSI will become imperfect due to limited backhaul. On the other hand, if the backhaul capacity is sufficient, limited feedback still causes interference by imperfect CSI. Therefore, it is necessary to jointly consider both effects. Marsch and Fettweis (2009) jointly considered limited feedback and backhaul constraints and evaluated some detection and coding mechanisms. Based on the analysis, how to adjust CSI feedback scheme under backhaul constraint is further investigated. Intuitively, according to different backhaul capacities, the cooperation mode can switch between joint transmission and interference suppression or partly joint transmission plus partly interference suppression. When the backhaul capacity is sufficient, BSs can fully cooperate to obtain cooperation gain. On the other hand, when the backhaul capacity is insufficient, only the interference information can be exchanged, and interference suppression is adopted.

In summary, the application of BS cooperation in real system encounters imperfect conditions, including limited computational capacity, synchronization issue, limited feedback capacity, and limited backhaul capacity. Candidate solutions have been given with three categories: clustering, feedback bits allocation, and mixed cooperation and interference management policy. These schemes enhance the feasibility of BS cooperation in practice. In the next section, key applications will be given.

Key Applications

The BS cooperation has been standardized in 3GPP (TR36.819 2012), termed as Coordinated Multipoint (CoMP). The imperfect conditions are considered in the standard. For instance, the cooperation clustering with cluster size 2 is suggested, the feedback policy includes explicit feedback and implicit feedback, and the CoMP categories include joint processing (fully cooperate), coordinated scheduling/beamforming

(partially cooperate), and so on. The techniques have been widely applied in 4G/LTE networks.

Recent progress and applications include BS cooperation under energy-efficiency constraint. For instance, in smart grid scenario, BSs need not only cooperate in signal domain but also in energy domain, so that the provided energy is sufficient for cooperation (Xu and Zhang 2015). In energy-harvesting scenario, where each BS is powered by renewable energy that is intermittent and imbalance, novel cooperation protocol is required to tackle the energy imbalance between cooperating BSs (Gong et al. 2016). The energy constraint can be viewed as another imperfect condition. Hence, the design under energy-efficiency constraint can be considered as an extension on the research of BS cooperation with imperfect conditions.

Big Data in 5G

Yue Wang and Zhi Tian
ECE Department, George Mason University,
Fairfax, VA, USA

Synonyms

5G; Machine learning; Next-generation wireless networks; Sparse signal processing; Wireless Big Data

Definition

The fifth-generation wireless systems, abbreviated as 5G (Andrews et al. 2014), are proposed as the next wireless and mobile communications standards beyond the current 4G standards. 5G networks not only aim at providing higher data rate, lower latency, larger capacity, and better customer experience than 4G but also commit

to fulfilling the Internet of things (IoT) with reliable and secure services at low costs (Atzori et al. 2010). To this end, 5G networks call for and rely on seamless operations of distinctive wireless technologies and solutions, including cognitive radio (CR) (Akyildiz et al. 2006), massive multiple-input multiple-output (maMIMO) (Larsson et al. 2014), millimeter wave (mmWave) communications (Rappaport et al. 2013), heterogeneous network (HetNet) architecture, cloud-based radio access, edge computing and caching (Hu et al. 2015), device and interference management (Asadi et al. 2014), etc. These revolutionary technologies deal with very wide radio spectrum, extremely high-frequency bands, dynamic spectrum access, large-scale antenna arrays, a huge number of devices, massive connectivity, context-aware computing, and so on. All these issues signify signal and data processing in regimes of exceedingly large volume, size, and dimension. As 5G services and technologies both support and contribute to an unprecedented amount of data traffic, the field of wireless communications has entered a Big Data era with imminent challenges and opportunities.

In the era of data deluge, Big Data refer to the kinds of data that are extremely large in terms of the size of available dataset and/or extremely complicated in terms of the processing complexity to separate, classify, and analyze the data. Thus, management of Big Data goes beyond the capability of conventional signal processing techniques and data analysis tools. Further, Big Data in 5G present unique challenges due to the characteristics of wireless and mobile data traffic and service expectations. Multi-domain resources, e.g., time, frequency, space, energy, and code, are intertwined in complex ways, and real-time content delivery are often expected by lightweight mobile devices. As a result, traditional processing and analysis techniques become inadequate to deal with such a huge amount of complex data within a tolerable elapsed time at affordable costs. Fortunately, recent advances and developments in machine learning and sparse signal processing illuminate pathways to embrace the challenges and opportunities from Big Data in 5G.

Historical Background

With the pervasive connectivity offered by 5G technologies, it is becoming a reality that we live in an immersive smart world with smart cities, smart networks, smart cells, smart grids, smart homes, smart vehicles, smart industries, smart devices, smartphones, smart sensors, and so on. The rapidly growing 5G and IoT applications generate an unprecedentedly vast amount of diverse data, which create and expand the regime of Big Data in 5G. On the one hand, the huge volume and high complexity of Big Data cannot be adequately and efficiently supported by legacy wireless technologies in spectrum access, resource allocation, and network management, all of which need to be revamped to address the Big Data challenges. On the other hand, Big Data, as new fuel for learning and predicting channel and network traffic behavior, offer great opportunities for improved system performance and much enhanced quality of experience in 5G.

In the regime of Big Data in 5G, although the dimension of signals and the quantity of data grow unprecedentedly large, there exist unique opportunities because of some useful properties, structures, and features exhibited in the underlying signals and data at both the signal and network levels. Harnessing such properties, structures and features not only allow to acquire data efficiently and process signals smartly but also enable prediction, control, management, and optimization of 5G networks in a proactive manner. Along this line, recent advances in powerful machine learning and intelligent signal processing techniques play key roles in not only supporting Big Data applications but also developing revolutionary 5G technologies in the Big Data era.

At the network level, powerful machine learning techniques have been employed to learn data traffic patterns in 5G networks for efficient network management and control. Machine learning, as a promising technology in artificial intelligence, gives machines the ability to learn without following strictly static program instructions by making predictions or decisions (Alpaydin 2004).

Generally speaking, machine learning enables a machine to learn the execution of some class of tasks T from experience E with respect to certain performance measure P , where the performance achieved at tasks in T is measured by P and can be improved with experience E . Machine learning approaches are typically classified into three broad categories, depending on the nature of the dataset for learning or the feedback available to a learning system. They are supervised, unsupervised, and reinforcement learning, where supervised and unsupervised learning indicate whether or not there are labeled samples in the input dataset and reinforcement provides feedback in terms of rewards and punishment to navigate the learning process. Recently, both the increase of available data volume and the improvement on hardware computational ability have contributed to the fast development of a new concept of deep learning (LeCun et al. 2015), which makes use of multiple hidden layers in an artificial neural network. This technique aims to mimic the way that the human brain processes light and sound into vision and hearing (LeCun et al. 2015).

At the signal level, intelligent signal processing techniques have been developed to exploit useful structural features of the complex channels and spectra in 5G systems for effective data acquisition and transmissions. Facing the large size and high dimension of sensing problems arising in wireless communications, compressive sensing (CS) (Candes and Wakin 2008), a.k.a. compressed sensing or compressive sampling, provides a new paradigm of simultaneous data acquisition and compression to effectively reduce the sampling costs of high-dimensional signals by utilizing the fact that typical signals of interest are often sparse in a certain domain via projection onto certain known basis. It is the sparsity of signals that enables CS techniques to reconstruct signals from far fewer samples than those required by the Nyquist sampling theory. As Big Data applications continue to grow in size and number, it is critical to deal only with measurements of data that are informative for specific inference tasks of interest, in order to limit the required sensing cost, as well as the related costs of storing or communicating Big Data. Alterna-

tive to CS for deterministic signals, a novel statistical signal processing framework, called compressive statistics sensing (CSS), is developed to leverage the statistical structure of random processes to enable compression (Romero et al. 2016). Capitalizing on parsimonious representations, CSS technology allows compression and reconstruction tasks to be addressed in broader applications, such as wideband spectrum sensing, frequency detection, direction-of-arrival estimation, power spectrum estimation, incoherent imaging, etc.

Foundations and Applications

When entering the era of wireless Big Data, it is of crucial importance to demonstrate how advances in artificial intelligence and signal processing can be used to overcome challenges and seek opportunities in future 5G wireless networks. Specific exemplary scenarios below describe some situations and applications in which different kinds of machine learning and sparse signal processing techniques play key roles in utilizing Big Data for wireless networks.

Supervised Learning

Supervised learning refers to the machine learning task of inferring an input-output mapping function from labeled training data, where the dataset contains observations of both the input objects and the resulting output values. Specific techniques include regression analysis, k -nearest neighbors (KNN) algorithm, support vector machine (SVM), and Bayesian learning (Alpaydin 2004). The regression analysis relies on a set of statistical processes for estimating the relationships among variables, which aims at predicting the value of one or more estimation targets. The estimation target is a function of the independent variables. The KNN and SVM algorithms are mainly used for classification. KNN classifies an object into a category based on a majority vote of the object's neighbors. That is, the object is assigned into a class that is most common among its k -nearest neighbors. In contrast, the SVM algorithm resorts to nonlinear

mapping, which transforms the original training data into a higher dimension where the data become separable. Then, SVM searches for the optimal linear hyperplane that can separate one class from another in the higher dimension. Bayesian learning is to compute and maximize the a posteriori probability distribution of a target variable conditioned on both the input signals and all of the training instances. Some generative models that can be learned with the aid of Bayesian techniques include the Gaussian mixture model, expectation maximization, and hidden Markov model.

In wireless communications, supervised learning can be used for training-based estimation and prediction of radio parameters. For example, in channel estimation for nonlinear MIMO systems where nonlinearities are present in either the transmitter or the receiver sides, a multivariate regression framework is modeled based on the SVM technique to utilize the MIMO channel multidimensionality (Sanchez-Fernandez et al. 2004). The use of the multidimensional regression enables to exploit the dependencies in the channel and then make each estimate less vulnerable to the added noise. In solving such a nonlinear MIMO channel estimation problem, an iterative reweighted least-squares algorithm is developed for the regression of multiple variables. Thanks to the benefits of SVM in solving nonlinear problems, this SVM-based channel estimation method can take advantage of the MIMO spatial diversity and is able to discover the dependencies between the transmitted and received signals.

For the link adaptation problem in MIMO-OFDM WiFi systems, supervised machine learning has also been successfully applied. In Daniels et al. (2010), the feature space is first defined to characterize the link quality by ordering the post-processing signal-to-noise ratio (SNR) and selecting those with high values as the most relevant link-level performance indicators. Then, the second step is to identify a mapping function between the defined feature set and the link configuration to fulfill the design objective. The mapping task is treated as a classification problem to determine the relationship between the channel

state and the configuration for adaptive modulation and coding, where KNN can be adopted as a classifier.

Another fruitful application is context-aware energy enhancement for mobile devices in IoT applications (Donohoo et al. 2014). KNN techniques have been applied to learn and utilize the spatiotemporal and device context to predict the device wireless data and location interface configurations that can optimize energy consumption in mobile devices (Donohoo et al. 2014). The experiment results in Donohoo et al. (2014) show that the successful rate of energy demand prediction exceeds 90% with the use of KNN algorithms.

Furthermore, Bayesian learning techniques can be used for learning and predicting spectral characteristics in cognitive radio systems and channel estimation in massive MIMO. For example, to solve the pilot contamination problem in massive MIMO systems, Wen et al. (2015) suggest to estimate both the channel parameters of the desired links in a target cell and those of the interfering links in other adjacent cells, in which channel estimation is carried out with the aid of Bayesian learning techniques. For cognitive radio networks, a cooperative wideband spectrum sensing approach is proposed to detect primary users via the expectation maximization algorithm (Assra et al. 2016). In Choi and Hossain (2013), a two-state hidden Markov process is designed to learn the spectrum occupancy of the primary user, whose presence and absence are mapped to a two-state observation space for Bayesian learning.

Unsupervised Learning

Unsupervised learning is to fulfill the learning task of inferring a function to describe the underlying structure or distribution from unlabeled data, which means the desired output values (e.g., classification or categorization outcomes) are not included in the observations (Alpaydin 2004). Since the data given to the learner are unlabeled, there is no evaluation of the accuracy of the learned structure as the output of the learning algorithm. As an example of unsupervised learning, k -means clustering is used for cluster analy-

sis in data mining, which aims to partition observations into k clusters where each observation belongs to the cluster with the nearest mean. The k -means clustering algorithm runs in an iterative manner. In each iteration, an object is assigned to the cluster whose centroid is the nearest one to the object and then each cluster and its centroid are updated by minimizing the in-cluster differences. The iterations will terminate until convergence is reached.

For wireless heterogeneous networks (HetNet) with densely deployed small cells, clustering is a common yet challenging task given the diverse types of operating networks/protocols and varied cell sizes. For example, small cells have to be carefully clustered to mitigate intercell interference, and terminal users also have to be clustered dynamically to avoid frequent cell handovers and achieve optimal offloading. In fact, the handover performance and intercell interference coordination critically determine the network efficiency and user experience. For cell and user clustering, several unsupervised learning methods can be used, such as k -mean clustering and principal component analysis (PCA). PCA can be viewed as a relaxed solution to k -means clustering, where the PCA subspace spanned by the principal directions is identical to the cluster centroid subspace. PCA transforms a set of potentially correlated variables into a set of uncorrelated variables a.k.a. the principal components.

In contrast to PCA, independent component analysis (ICA) is a statistical technique for revealing hidden factors that underlie sets of data variables. Based on these underlying factors, ICA decomposes the data variables into a set of independently additive components. This is done by assuming that the subcomponents are non-Gaussian and mutually independent from each other. ICA is useful for blind source separation. In Qiu et al. (2011), ICA is used in a CR-based smart grid system to recover the simultaneous wireless transmissions of smart utility meters, where the power utility station applies ICA to blindly separate the signals received from all the smart meters before the signals can be decoded, by utilizing the statistical properties of the signals.

Reinforcement Learning

Reinforcement learning is inspired by behaviorist psychology to deal with learning tasks when the feedback of the instantaneous reward is available. It is concerned with how learning agents ought to take actions in an environment based on feedback, in order to maximize the cumulative reward over time (Otterlo and Wiering 2012). The environment in reinforcement learning is typically formulated as a Markov decision process (MDP). The main differences between the classical inference techniques and reinforcement learning algorithms include: (1) the reinforcement learning techniques do not request any prior knowledge about the MDP, and (2) they target large-scale MDPs where classical methods become infeasible. Reinforcement learning focuses on the online performance, which enables to reach a balance between exploration of uncharted territory and exploitation of obtained knowledge. Such a trade-off can be achieved via the multiarmed bandit (MAB) and finite MDPs (Kaelbling et al. 1996). MDP describes a discrete-time stochastic control process and provides a framework for modeling the decision-making situations in which the outcomes are partly random and partly under the control of a decision-maker. At each step, the MDP stays in a certain state, and the decision-maker may choose any legitimate action that is available in the current state. At the following step, the MDP randomly moves into a new state and gives the decision maker a corresponding reward. The probability that the MDP moves into its new state is influenced by both the selected action and the system's inherent transitions. In this sense, the new state depends on the current state and the action selected by the decision-maker. Meanwhile, the state transition probability is conditionally independent of all previous states and actions, which makes the MDP satisfy the Markov property. MDP usually assumes that the state is known when action is to be taken. However, if this assumption is not guaranteed, then the MDP problem becomes partially observable, a.k.a. POMDP. The POMDP models an agent decision process where the system dynamics are determined by an MDP, although the agent is unable to directly observe the underlying state

and only has partial knowledge. Thus, the agent must maintain a probability distribution of the possible states based on a set of observations and observation probabilities and the underlying MDP. In the learning task for the MAB problem, an agent seeks to simultaneously perform exploration and exploitation: the former is to acquire new knowledge, and the latter is to optimize the decisions based on existing knowledge.

For decision-making in 5G wireless systems, the terminal users in a network can be regarded as agents, and the network constitutes the environment of the MDP/POMDP models. The applications of reinforcement learning include transmit power control in energy-constrained systems, channel selection in device-to-device (D2D) communications, dynamic spectrum access in CR networks, and so on. For example, future IoT systems may feature in wireless energy harvesting sensors that operate using energy harvested from environmental sources such as the sun, wind, vibrations, etc. For these sensors, energy management is crucial to ensure continuous and reliable operation with minimized power outage. In Aprem et al. (2013), the problem of transmit power control with packet retransmissions is formulated as making a sequential decision to achieve optimal outage probability performance. Through acknowledgement (ACK) and negative-acknowledgement (NACK) feedback messages, the channel information is implicitly provided to the sensors, which can be exploited in deciding the transmit power level for subsequent transmission attempts. Since the ACK and NACK messages only reveal partial channel information to the sensors, this problem is cast as a POMDP formulation. Accordingly, computationally efficient solutions have been developed based on the maximum likelihood criterion and the voting heuristic policy (Aprem et al. 2013).

In the context of D2D communications, distributed and autonomous channel selection is considered as an underlay to a cellular network. D2D users directly communicate with each other by exploiting the cellular spectrum, while

their individual decisions are not governed by any centralized controller. Self-interested D2D users competing for access to optimize their own performance form a distributed system, where the transmission performance actually relies on channel availability and quality. However, such information is hard to acquire for autonomous D2D users. Further, the adverse impact of D2D communications to cellular systems should be minimized. Under these limitations, a network-assisted distributed channel selection approach is proposed by modeling a multiplayer (MP) MAB game with broadcast side information indicating channels selected by other D2D users (Maghsudi and Stanczak 2015). In this MP-MAB game, each D2D user is viewed as a player, and the channels are regarded as multiple arms, where selecting a channel corresponds to pulling an arm. Then, a distributed solution is developed by combining no-regret learning and calibrated forecasting for multiplayer stochastic learning problems. Similarly, in CR scenarios, the problem of dynamic spectrum access of decentralized secondary CR users can also be modeled as a MP-MAB game (Liu and Zhao 2010), where each CR user independently searches for spectrum opportunities without exchanging sensing information with others.

Deep Learning

Deep learning refers to the learning techniques that allow computational models to take on multiple processing layers in order to learn representations of data with multiple levels of abstraction (LeCun et al. 2015). Deep learning has led a new trend in artificial intelligence by providing a powerful set of techniques for learning via deep neural networks (DNN). In DNN, connections and interactions of neurons from layer to layer contribute to feature extraction and transformation, where each layer uses the output from the previous layer as the current input. Such a topology allows a biologically inspired programming paradigm where an agent is able to learn from observational data via representing and utilizing the abstract features among data (Schmidhuber 2015). By continuously learning

multilevel features of the data, higher-level features are learned and formulated from lower-level features to form a hierarchical representation. In this way, deep learning translates the features of data into compact intermediate representations over layered structures, which can be used to remove redundancy and detect saliency. In the era of 5G, wireless traffic and user data are experiencing a tremendous growth due to pervasive devices, ubiquitous connections, and diverse services and applications. Different from the centralized and static architecture of conventional cellular networks, future wireless networks and systems are moving toward decentralized and flexible network architectures. In this context, deep learning provides useful tools to acquire underlying trends, predict upcoming events, and harvest correlations and statistical probabilities, given a huge amount of available data for training. Such efforts enable 5G wireless networks to make proactive decisions such as proactive resource allocation by taking advantage of context awareness and edge computing and caching (Wang et al. 2014), which thereby improve network performance and efficiency. In return, these 5G techniques offer pervasive network connectivity for data collection and transmission, which make it possible to enhance Big Data analytic tools and deep learning techniques within 5G networks for accurate content popularity estimation and prediction. After traffic content learning, popular contents are cached in the intermediate servers so that demands from users for the same content can be accommodated easily without duplicate transmissions from remote servers (Bastug et al. 2014). As a result, redundant traffic can be significantly eliminated to save precious wireless network resources.

In addition, given the available large volume of user and network data, Big Data analytics are inherently synergistic with the trend of software-defined networking (SDN) in 5G (Haleplidis et al. 2015), which refers to network programmability by initializing, controlling, managing, and updating network behavior dynamically via open interfaces. While SDN has emerged as a promising networking solution, opening up interfaces gives rise to the risk of security

threats to both user and network data. To solve such problems, neural network can be adopted for anomaly detection in SDN environments. In Jadidi et al. (2013), to protect a network from attacks, a flow-based anomaly detection algorithm is developed based on a multilayer perceptron and gravitational search scheme, in which a neural network uses a large volume of traffic data to classify benign and malicious flows with high accuracy.

Wideband Spectrum Sensing

At the signal level, Big Data challenges arise primarily from the large size and high dimension of transmitted and received signals that 5G systems have to cope with. For instance, cognitive radio (CR) has been acknowledged as an important technology for dynamic spectrum access in future 5G, which aims to overcome the dilemma between radio frequency (RF) scarcity and spectrum underutilization. The first and key task in CR is to perform accurate and fast spectrum sensing in order to determine the spectrum occupancy of existing (primary) users and identify potential transmission opportunities for (secondary) CR users. To harvest the benefits of open spectrum access and dynamic spectrum sharing, spectrum sensing is usually conducted over a very wide range of frequency bands. In the wideband regime, a major challenge stems from the high costs in RF signal acquisition, which hinders the implementation of fast and accurate spectrum detection. On the other hand, the spectrum underutilization over most assigned frequency bands induces widespread sparsity in the frequency domain. Capitalizing on such sparseness of the underutilized spectrum in open-access networks, CS techniques have been tailored and applied for wideband spectrum sensing using a much smaller number of samples than that required by the Nyquist sampling rate (Tian and Giannakis 2007; Polo et al. 2009). This is because the sampling rate in CS is dictated by the sparsity order of the signals, rather than the large dimension of the original signals. Since the average spectrum utilization of most frequency bands is below 20% at a given time and location (Akyildiz et al. 2006), the CS approach allows for sampling

at a small fraction of the Nyquist rate without loss of sensing accuracy.

Considerable research efforts have been devoted to realizing the potential of CS-based sensing and sparse signal processing in wireless CR systems under practical operating scenarios. For instance, in practical wireless environments, the actual sparsity order of wideband spectrum is usually unknown a priori or even dynamically changing over time. To circumvent this problem, a concept of sparsity order estimation is proposed in Wang et al. (2012a), which can be applied to design a two-step compressive spectrum sensing solution for wideband CR (Wang et al. 2010). Wireless fading constitutes a major performance-degrading factor to sensing techniques in practice. To cope with the fading effects, collaborative spectrum sensing among distributed CR users provides an effective way to improve the sensing performance (Zeng et al. 2010). For wideband collaborative CR systems, to jointly collect both performance gain and complexity gain, a cooperative spectrum sensing solution is designed based on matrix rank minimization techniques (Wang et al. 2011). Therein the spectrum measurements of all collaborative CR users are modeled to possess a decent low-rank property. Accordingly, a nuclear norm minimization problem is formulated to jointly identify the nonzero support and hence the overall wideband spectrum occupancy, in which the low-rank property enables efficient utilization and desired tradeoff between detection diversity and sampling costs (Wang et al. 2012b).

Under the conventional centralized network architecture for spectrum sensing, although the sensing performance can be globally optimal, the energy costs in reporting local information to the fusion center and conveying global decisions back to the CR users can be undesirably high. Alternatively, decentralized cooperative spectrum sensing becomes attractive for its low communication overhead and robustness to node and link failure. Decentralized schemes have been developed based on consensus techniques (Bazerque and Giannakis 2010; Tian 2008). These algorithms adopt a consensus averaging technique, where the average value of all the local spectrum

decisions is computed in a decentralized manner and taken as the global decision.

The framework of consensus-based collaborative sensing has been extended to address the technical hindrance in practical multi-hop CR networks. In a CR network adopting dynamic access, there is no guarantee on stringent synchronization to ensure that all CR users stay silent during the sensing stage. Further, due to the multi-hop nature, a CR user during the sensing stage may be subject to distinct spectral emissions from sources within its local area, such as other coexisting CR users in the transmission mode, mistimed cooperative CR users in the sensing mode, or local interference. These individually received spectral components, termed as spectral innovations, are sparse but complicate the cooperative task of detecting the common spectrum support of primary users. To deal with this complex but practical problem, decentralized multi-hop cooperative spectrum sensing solutions have been developed in Zeng et al. (2010) and Zeng et al. (2011), in which each CR user estimates the common spectrum of primary users and its own local spectral innovation in an alternating manner and exchanges proper information with neighboring CRs to reach global fusion and consensus on the estimated primary users' spectrum occupancy.

Besides the wide bandwidth and wireless fading, noise uncertainty raises another critical issue that degrades the performance of spectrum sensing. Cyclic feature detection as a kind of statistical signal processing technique works robust under noise uncertainty and low SNR (Gardner 1991) but requires high-rate sampling which is very costly especially in the wideband regime. To solve this problem, a compressive cyclic feature detection technique has been developed for wideband spectrum sensing by exploiting the unique sparsity property of the two-dimensional cyclic spectra of cyclostationary signals (Tian 2011). Along this line, a new compressed covariance sensing framework is proposed for extracting useful second-order statistics of wideband random signals from digital samples taken at sub-Nyquist rates (Romero et al. 2016; Tian et al. 2012).

Sparse Channel Estimation

To meet the growing demands for high-rate and large-capacity wireless services, massive multiple-input multiple-output (MIMO) technology and millimeter wave (mmWave) communications have emerged as a natural pair to provide a promising option for 5G networks. In MIMO communications, the channel state information (CSI) is required via channel estimation for transmitter design and receiver demodulation. However, the large number of antennas in massive MIMO systems results in a large-size channel matrix, which is costly to estimate, because traditional channel estimation techniques would consume heavy resources in terms of training symbols and CSI feedback. To reduce such heavy training overhead, CS has been advocated for CSI estimation in mmWave MIMO systems (Bajwa et al. 2010; Schniter and Sayeed 2014; Alkhateeb et al. 2014; Gao et al. 2016; Wang et al. 2016a, b). By exploiting the sparse structure of mmWave MIMO channels due to the limited multipath scattering, the CS-based approach can estimate the CSI from a relatively small set of compressively collected training symbols. In Bajwa et al. (2010) and Schniter and Sayeed (2014), the task of estimating sparse multipath channels is formulated as a sparse vector recovery problem by vectorizing the sparse channel matrix and representing it within a three-dimensional angle-delay-Doppler space. Subsequently, sparse signal recovery techniques can be applied to acquire the vectorized sparse channel from compressive measurements within a short sensing time (Schniter and Sayeed 2014; Gao et al. 2016). In Alkhateeb et al. (2014), an adaptive CS-based algorithm is proposed to estimate the sparse channel with hybrid analog/digital hardware architecture. In Wang et al. (2016a), a diagonal-search greedy pursuit algorithm is developed to estimate the second-order statistics of the sparse MIMO channel. To reduce the sensing time and computational complexity caused by the vectorization operation, a fast channel estimation solution is developed in Wang et al. (2016b), which directly decouples the original channel estimation problem into three reduced-size subproblems, i.e., angle-of-arrival

(AoA) estimation, angle-of-departure (AoD) estimation, and fading coefficient estimation, which can be solved in a sequential manner.

The CS-based channel estimation techniques for mmWave MIMO systems implicitly rely on the assumption that the values of the AoD/AoA of sparse paths fall on some known grid. However in practice, the AoD/AoA can be continuously valued off the grid, in which case the CS-based methods may suffer from the power leakage effect due to basis mismatch of the on-grid assumption (Chi et al. 2011). To circumvent the on-grid assumption, gridless channel estimation solutions can utilize the two-level Toeplitz structure of mmWave massive MIMO channel by applying two-dimensional (2D) atomic norm minimization (ANM) to estimate the continuous-valued channel state information with super resolution. The 2D ANM is a two-level structure-based optimization approach where the Vandermonde structure of the transmit/receive array manifold is captured by a two-level Toeplitz matrix, which can be constructed from the received array data via semidefinite programming (SDP). Such a gridless channel estimation approach attains super-resolution AoD/AoA estimation accuracy within a very short sensing time, possibly from measurements collected at a single-time snapshot.

Noticeably, the computational complexity of the SDP-based ANM formulation is decided by the numbers of transmit and receive antennas used for MIMO channel estimation. As a result, the computational complexity goes up quickly as the antenna size increases and may become intractable for terminal devices. To reduce the high complexity, an efficient truncated 2D gridless channel estimation solution is proposed for mmWave massive MIMO systems (Wang et al. 2017). It reformulates the original full-size ANM to a truncated ANM (T-ANM) version by activating a small part of transmit/receive antennas. The T-ANM approach is motivated from an important fact that the mmWave MIMO channel provides not only the two-level Toeplitz structure but also a salient low-rank property due to the limited scattering propagation at mmWave frequency. Further complexity reduction is accomplished by

introducing an alternative form of ANM, termed decoupled ANM (D-ANM) (Tian et al. 2017). It is another optimal ANM formulation for gridless 2D harmonic retrieval problem, which adopts a new matrix form set of atoms to naturally decouple the joint observations in both AoA and AoD dimensions without loss of optimality. The D-ANM strategy reformulates the original large-scale 2D problem into two one-level Toeplitz matrices, which can be solved by simple 1D estimation with automatic pairing. Therefore, D-ANM dramatically reduces the constraint size in SDP-based ANM formulation, thus greatly reducing the overall computational complexity.

Summary and Outlook

This article reviews emerging technologies and advances achieved in both machine learning and sparse signal processing and focuses on data analytic tools that can be used in future 5G wireless networks. To demonstrate their broad applications in various wireless systems, selected examples are illustrated, including CR, HetNet, mmWave, massive MIMO, software-defined networking, etc.

There are still a range of open questions in Big Data analytics for 5G wireless networks. For instance, it is quite challenging to apply machine learning to gain full awareness of the RF environments over space, time, frequency, and location, due to the dynamic nature and the lack of labeled data. As opposed to computer vision and speech recognition where the output of machine cognition can be readily compared and verified against human visual and auditory perception, no such option is available for radio signals.

Definition

Big data networks provide a distributed infrastructure for storing, transmitting, and processing a huge volume of data to extract useful information from the data.

Historical Background

The world is generating data much more fast than before. It is predicted that the total data generated in the world doubles every 2 years (Gantz and Reinsel 2012). The huge volume of data appears in various domains and applications, e.g., large graph or complex graph for social networks (Nie et al. 2017; Strogatz 2001), protein-protein interaction (PPI) networks (Stelzl et al. 2005) in bioinformatics, huge number of searching requests in searching engine, and the big data generated from Internet of Things (IoT) devices (Sun et al. 2016).

How to efficiently store and process the huge volume of data is an important technique issue. The idea of leveraging the resources from a set of computers to enhance processing capability and to manipulate a large volume of data can be traced back to early distributed computing systems in 1970s and 1980s (Gligor and Shattuck 1980). High-performance computing (HPC) (Dowd et al. 1998) and grid computing (Chervenak et al. 2000) played important roles in processing large volume of data since 1990s, and they are still important platforms to perform computational-aware tasks nowadays.

In 2006, Amazon released its elastic computer cloud (EC2) platform (Buyya et al. 2008), which provides a platform to aggregate resources from a set of powerless computers to obtain the required capability to process a large volume of data. This is different from previous approaches based on HPC. In the same year, Google released MapReduce (Dean and Ghemawat 2008) and Bigtable (Chang et al. 2008), which support parallel processing of big data in a cluster containing a large number of computers and managing a huge number of structured data in a cluster. The Spark framework (Zaharia et al. 2010) improves efficiency by using in-memory computation. Moreover, Spark supports iterative processing which are necessary in many machine learning tasks.

Foundations

Big Data VS. Networks

When the volume of data becomes huge, the data cannot be stored and processed on a single computer, and we have built networking systems to store, transmit, and process the big data. First, as the data exceeds the capability of a single computer node, it is necessary to build a network to connect a large number of nodes storing the data and exchange the data between them efficiently. This stimulates the development of data centers. Second, to process the big data, we need new network computing paradigms to process the data quickly and in parallel, such as MapReduce and Spark.

Big Data Storage

The huge volume of data are usually stored in *data centers* (DCs) (Al-Fares et al. 2010; Bari et al. 2013). A data center (Bari et al. 2013) is an infrastructure that consists of servers, storage and network devices, and auxiliary facilities such as power distribution systems and cooling systems. The communication infrastructure used in a DC is called a data center network (DCN). In order to improve the efficiency for big data storage and support fast processing of big data, current research in data center networks mainly focus on the following aspects:

- *Topology design:* The topologies used in DCNs can be classified into two categories: switch-centric topology and server-centric topology. In switch-centric DCN topologies, the network connection and routing functions are performed on switches, while the servers are mainly used for data storage and computation. Typical switch-centric topologies include Fat-Tree and VL2. In contrast, in server-centric topologies, the function of interconnection and routing are performed on servers, while the switches provide only simple crossbar functions. Typical server-centric topologies include Dcell, BCube, and uFdx.
- *TCP optimization:* Due to the special features of DCNs that are different from traditional Internet, performance of traditional TCP congestion control protocols might degrade significantly in some cases. One such feature is TCP Incast (Wu et al. 2013): when a client sends data request to many servers simultaneously and these servers return data to the client at the same time. In such a case, the buffer of switches will overflow, which will greatly degrade the throughput of the network. Researchers propose several techniques to address the TCP Incast problem. Another hot research issue in TCP for DCNs is multipath TCP (MPTCP). In topologies like Fat-Tree and BCube, there are multiple paths between a pair of hosts. In many cases, MPTCP can significantly increase the data throughput in DCNs.

Processing Platforms

Cloud computing (Armbrust et al. 2010) provides powerful computation capability to process the big data stored in data centers. According to the provided services, cloud computing can be classified into three categories:

- *Infrastructure as a Service (IaaS)*: In this type of service model, the cloud provides a set of highly scalable and automated computer resources to users in the form of bare hardware. The users can install operating system, deploy applications, or develop programmes by themselves. Examples of IaaS include Amazon AWS and Rackspace. The users can exploit the high scalability of IaaS, which allows them to dynamically scale up resources on demand instead of buying hardware outright.
- *Platform as a Service (PaaS)*: In this type of service model, the cloud provides a platform with components containing certain software for some applications. PaaS allows the customers to develop, run, and manage their applications on the platform, without building and managing low-layer infrastructure issues as in IaaS. PaaS provides a framework on which the users can create their customized applications. Examples of PaaS include Google App Engine and Windows Azure.
- *Software as a Service (SaaS)*: In this type of service model, the cloud delivers applications to users through Internet. In the SaaS model, the user needs not to download and install applications on their individual computers. The customer can focus on maintenance and support of their application, while the detailed technical issues such as data, servers, storage, and middleware are all handled by the software vendors. Examples of SaaS include Google Apps, Dropbox, and Salesforce.

Big Data Processing Framework

MapReduce (Dean and Ghemawat 2008) is a programming model for processing parallelizable

problems across huge volume of data using a cluster of computers. MapReduce can process both unstructured data stored in a filesystem or structured data stored in a database. It can take advantage of the locality of data, processing the data near the place where the data is stored in order to minimize communication overhead. When using MapReduce, the user specifies a map function and a reduce function. The map function takes a key/value pair as input and generates a set of intermediate key/value pairs. The reduce function merges the intermediate values with the same intermediate key.

A MapReduce program usually contains three steps:

- *Map*: In the map step, each worker node applies the map function to its local data and writes the output of the map function to a temporary storage. There is a master node that is in charge of partitioning data and send data to different worker nodes for processing, ensuring that only one copy of redundant input data is processed.
- *Shuffle*: In the shuffle step, the worker nodes redistribute data based on the output keys, such that all data belonging to one key are located on the same worker node.
- *Reduce*: In the reduce step, the worker nodes process each group of output data and merge the intermediate results in parallel.

There are two limitations of MapReduce. First, it cannot handle iterative algorithms, but a large number of data processing algorithms (e.g., many machine learning algorithms) are iterative. Second, its performance is greatly affected by the I/O operations. To overcome the limitations of MapReduce, the Spark (Zaharia et al. 2010) framework is developed. Compared with MapReduce, Spark significantly improves efficiency by doing in-memory computation. It provides caches to support iterative computation and multiple data sharing, which reduces cost in data I/O. It decreases the cost in writing intermediate result to HDFS by using the directed acyclic graph (DAG) model and reduces

redundant sorting and I/O operations by using multi-thread pool. Spark supports more flexible APIs than MapReduce and supports more languages.

Machine Learning for Big Data Processing

Machine learning are a powerful technique to extract useful information or knowledge from big data. For example, face recognition based on deep learning has been successful in many security-related applications in recent years. Machine learning-based big data processing usually requires a large volume of labelled training data, with which we can build very powerful models that sometime even outperform human being in some special tasks. Recently, how to design suitable network structure for machine learning models that run on a large number of computing nodes have attracted researcher's attention. This includes designing optimized network structure to reduce parameter transmission in learning models and adaptive learning model execution framework to reduce execution latency of the learning model.

Big Data Network Requirements

Different from traditional data processing, big data processing faces many challenges. First, besides structured data, in big data applications, most data are only partially structured or even unstructured. Second, the volume is extremely large, in the magnitude of PB or even EB. Third, the relationship among data is complex and unknown, making it difficult to use existing approaches to extract useful information from the data. As pointed out in Al-kahtani (2016), the challenges pose some requirements on big data networks, some of which are listed as below.

- *Network resiliency*: The availability of a network is critical to communication of distributed resources. Path diversity and failover can help improve the resiliency of the networks to failures. Path diversity means to utilize different routes rather than a single fixed route between a pair of communicating nodes. Failover means to have the ability to recognize failures and switch over to an alternate path quickly.
- *Network congestion mitigation*: When many big data applications launch at the same time, their data flow might work in a burst mode and might cause problems like Incast. This might cause congestion problems and consequently increase response latency. As previously described, network congestion can be mitigated by designing network topology and optimizing over TCP.
- *Network performance consistency*: Because the processing time in big data applications is usually dominated by the computational time rather than data transmission delay, big data networks are not affected a lot by network latency. For big data applications, one more important issue is to maintain high synchronicity, which refers to that different jobs in big data applications need to be executed in parallel in order to assist in accurate analysis. In such cases, any large decrease in network performance may trigger failures in the outcome.
- *Network future scalability*: As more and more big data applications will be ported to data centers, it is important for the data center architecture to have the ability of scale-up adaptively according to the requirement of applications.
- *Application awareness*: Big data network architecture typically use computer cluster environments such that the nodes can build large data sets. Different applications might pose different requirements on the performance of the data center. For example, some applications might need high bandwidth, but others might focus on low latency. If the network aims to support different tenants' applications with different requirements, it needs to support, differentiate, separate, and process various workloads with different requirements. When designing a big data network, the designer needs to consider all factors including coexistence issues of data flows, processes, and application resources.

Key Applications

Big data networks have been utilized in various domains to process huge volume of data. Some applications that utilize big data networks are listed below.

- *Key protein complexes identification:* How to identify the key protein complexes and their function models from a protein-protein interaction (PPI) network are most computation-intensive problems in the bioinformatics research (Stelzl et al. 2005). The high time complexity of traditional algorithms make them unsuitable for large-scale PPI networks. Currently, MapReduce and Spark have been used to process large-scale PPI networks (You et al. 2014; Harnie et al. 2017).
- *Recommendation systems in E-Business:* In E-commerce companies such as Amazon and Alibaba, how to predict the preferences of different customers and make correct recommendation for them is a key issue. Amazon makes recommendation decisions with big data, which significantly increases its profit. Amazon uses *item-to-item* collaborative filtering to obtain accurate recommendation results, which relies big data network to handle billions of customers and products.
- *Community discovery in social networks:* Community detection and discovery in large-scale social networks is another typical application that relies on big data network to process huge datasets. Large social media networks usually have a huge number of users, e.g., Facebook has more than 2 billion daily active users by 2017. In order to efficiently detect and discover communities in such large-scale social networks, MapReduce has been used (Guo et al. 2015).

Definitions

Big network data refers to big data that is generated or collected in different networks varying from social networks, communication networks, transportation networks, the World Wide Web (WWW), biological networks, citation networks, etc., that is, datasets in networks that are so voluminous and complex that traditional data processing methods are inadequate to deal with them, while advanced data analytics methods are needed to extract value from them. The five dimensions to big data known as Volume, Variety, Velocity, Veracity, and Value still apply to big network data.

Historical Background

The evolution of big network data is in line with the evolving of large-scale distributed systems (Akyildiz et al. 2002; Armbrust et al. 2009; Fernando et al. 2013), the Internet, and networking technologies, which turned the processing of big data and obtaining valuable information from the big data increasingly challenging and difficult. Namely, the scale and complexity of network data begin increasing with the invention of computer networks designed to exchange data in the 1950s. From the establishment of Wide Area Networks (WAN) in 1960s, the wide adoption of TCP/IP in 1970s to the most recent development in 5G communication networks, volumes, types, and generation speeds of network data have been increasing dramatically.

One of the first milestones in the history of network data was the arrival of Salesforce.com in 1999, which is a pioneer by delivering enterprise applications via a simple Internet website hosted in servers. This allows the data being generated in the servers with rationale databases. The next development of network data was Amazon Web Services in 2002, which provided a series of cloud-based services including storage and computation. Meanwhile, by 2006, Facebook and Twitter both became available to users throughout the world, which accelerates the generation of not only user data but also large-scale graph data that characterize user relations. With the increasing number and advancement of such cloud services and online social networks, more and more enterprise, governments, and individual users are relying on cloud services for either high efficiency for their daily businesses or low cost for expenditure reduction. With the continuous running of such cloud services, large volumes of data generated at unprecedented rates from sensors, emails, Internet transactions, click streams, user preference of purchases, etc. are getting attention of many enterprises as it poses valuable patterns and business insights.

In the past decade, the availability and growing expectation of ubiquitous connectivity is one of the most transformative technology driving big network data. Whether it is for checking

email, carrying a voice conversation, or browsing web pages, mobile users can access these online services regardless of location, time, or circumstance: at the office, on a subway, while in flight, etc. Such ubiquitous mobile accesses to services allow the users to generate data anywhere any-time at a unprecedented rate.

Most recently, the techniques of 5G, Software-Defined Networking (SDN) and Network Function Virtualization are pushing the big network data into a new age. On one hand, these techniques further enlarges the capacity of networks by allowing more users, thereby future contributing to the volumes and diversity of big network data. On the other hand, they enhance the efficiency of big data analytics by allowing more efficient data transfers in networks. For example, SDN that separates the network control logic (the control plane) from the data forwarding plane is a new promising technology to enable efficient data transfers via the flexible management of network resources.

Foundations

Big network data involves the data that is related to any networking technologies, varying from communication networks to social networks. According to types of networks, big network data usually can be classified into the following categories:

- **Big data in wireless networks:** Given the myriad different use cases and applications of wireless networks, there exist dozens of wireless networking technologies, each of which has its own performance characteristics and optimized for a specific task and context. For example, there are over a dozen of widespread wireless technologies in use: WiFi, Bluetooth, ZigBee, NFC, WiMAX, LTE, HSPA, EV-DO, 3G standards, satellite services, etc. Big network data in different wireless networks is diverse in terms of collecting, storing, and processing methods, as they are designed for different usage scenarios and handle user data in different ways. For example, wireless sensor networks focus on the collection of multi-dimensional (location, time) sensing data in an energy-efficient and bandwidth-saving manner (Akyildiz et al. 2002; Cardei et al. 2002; Liang 2006), and thus various data collection, data compression, data transmission, and coding methods are proposed. Internet-of-Things (IoT) networks are another major source of big network data. Given that sensors are used in nearly all industries, the IoT is expected to produce a huge amount of data (Ahmed et al. 2017). The volume and diversity depend on specific application of the IoT.
- **Big data in cloud networks:** With an exponential increase in cloud services for smart device users, there is an increase in the bulk amount of data generated by the services. Generally, most service providers, including Google, Amazon, Microsoft, and so on, have deployed a large number of geographically distributed data centers that are interconnected by wide-area networks – known as *cloud networks*, to process huge amounts of big network data so that users can get quick response. There are two directions related to big data processing in such cloud networks. One direction is the design of efficient parallel processing frameworks and tools to achieve real-time process of big data within one data center. Hadoop and SPARK are examples for this purpose, which are widely used by cloud service providers (Singh and Reddy 2014; Reyes-Ortiz et al. 2015; Zaharia et al. 2016). Another direction is the design of novel network architectures, communication protocols, routing algorithms, etc. to alleviate the bottleneck of underlying network infrastructures in terms of transfer congestions due to big data transfers (Gu et al. 2014; Jiao et al. 2014; Xia et al. 2016, 2017a,b).
- **Big graph data:** Social networking sites (e.g., Facebook, Twitter, and LinkedIn) keep expanding in terms of the online active users and the data generated by the

users. The data in such social networking sites can usually be modeled as graphs, with their nodes representing users and edges representing relations. Such graph data are being generated at an unprecedented rate; they are now measured in terabytes and heading toward petabytes, with more than billions of nodes and edges. For example, it is reported that WWW now contains more than 50 billion web pages and more than one trillion URLs (WWW 2018). A recent snapshot of the friendship network Facebook contains 800 million nodes and over 100 billion links (Facebook 2018). One of the most fundamental problems related to such big graph data is finding cohesive groups that can be regarded as *communities* such as friends, co-workers, neighbors, etc. (Zhou et al. 2009). For example, in web graphs, they are likely groups of web pages about the same or related topics. Another fundamental problem is to identify highly “influential” communities and individuals from such large networks as they govern the entire network behaviors and thus bring enormous social and economic benefits (Ding et al. 2007).

- **Big monitoring data:** The complexity of large-scale networks is constantly increasing. With more services being offered and the continuous growth of bandwidth-hungry video-streaming services, network and server infrastructures are becoming extremely difficult to monitor, since the volume and complexity of monitoring data are increasing in an unprecedented rate. Network Traffic Monitoring and Analysis (NTMA) is to process big, heterogeneous, and high-speed data related to various status of the networks (Bär et al. 2014). Although big monitoring data preserve all the “V”s of big data, the traditional techniques for general purpose big data cannot be directly applied to NTMA. The reason behind is that traditional big data technologies lack efficient and effective methods for real-time traffic analysis (Bär et al. 2014; Liu et al. 2014).

Key Applications

Efficient and effective analysis of big network data has wide applications in many areas spanning from Internet-of-Things (IoT) industrial services to every economic aspect of people’s daily lives. The key applications of big network data and its corresponding analytic techniques are summarized as follows, from the perspectives of Internet of Things, communication and cloud services, trading promotion and decision-making, and innovative networking technologies.

- *Internet of Things:* The efficient and continuous processing of big network data in IoTs can contribute to the correct operation and development of IoT applications. For example, data collection efficiency in IoTs can be promoted dramatically if analytic results on big network data show a smart distribution of sensor locations where important values are obtained. In addition, to generate benefits from IoT, enterprises need analytic techniques for big network data, via which they can collect, manage, and analyze a massive volume of data from sensors in a scalable and cost-effective manner. In this context, big network data can assist in consuming, reading, and analyzing diverse enterprise data on information that is collected by enterprises.
- *Network and cloud services:* Big network data is a significant part of network and cloud services. The efficient analysis of big network data in return can contribute to the advancement of such services. For example, the users’ preference of cloud services can be obtained through analyzing user access information, thereby contributing new cloud services. From the views of network service providers, by analyzing the locations of their mobile users based on big network data, strategic deployments of their infrastructures can be performed to maximize the revenue of network service providers.
- *Trading promotion and decision-making:* Identifying highly influential communities

and individuals based on big graph data in large-scale networks is significant in terms of social and economic benefits. For example, identifying highly influential communities in a large collaboration network can help to find world-leading research teams and potential research directions. Also, identifying highly influential communities in trading and economic networks will enable enterprises to better promote products and enhance business opportunities. On the other hand, identifying most influential individuals is significant to disparate applications, including accelerating information propagation, controlling rumors and diseases, designing search engines, and understanding hierarchical organization of social and biological networks.

- Innovative networking technologies: Big monitoring data in networks characterize the running status of a network that is supported by a specific networking technology. For example, by consistently monitoring and analyzing security attacks in networks, novel security protocols can be designed to prevent future security breaches. Also, analytic results based on the monitoring data related to network resource allocations will have a major impact on the design of network resource allocation strategies and mechanisms.

Definition

A blockchain is a linear collection of data elements called *block*, where all blocks are linked to form a chain and secured using cryptography, and newly generated blocks are continuously chained to the blockchain in an untrusted environment. To date, there is still lack of formal definitions on the blockchain that can be accepted by both the academia and industry.

Historical Background

The Blockchain technique is derived from the Bitcoin which is first proposed by Nakamoto in 2008. The primary objective of Bitcoin is to propose a secure payment system without a trusted party such that online payments can be sent directly from one user to others without going through a financial institution. This is achieved by a distributed ledger which accounts for the ownership of coins. The key challenge is to resist double spending attacks, where an adversary could issue two transactions in parallel so as to transfer the same coin to different recipients. Essentially, enabling the distributed ledger to be secure against double spending attacks boils down to the Byzantine Generals problem (BGP). Existing solutions to solve BGP mainly focus on the permission model, where the participants in the system are predetermined (or participants know each other). However, the participants who maintain the ledger in a secure digital payment system are under a permissionless model, where anyone can join or leave the system without permitted by a centralized or distributed authority.

Bitcoin first achieved consensus on the distributed ledger in the permissionless model, where it cleverly integrates existing primitives and solutions from decades of research into one system to solve the fundamental problems existing in digital currencies in a practically viable way. Bitcoin is also the first cryptocurrency that is widely applied in large-scale networks. Due to the success of Bitcoin, its underlying technique called “blockchain” is extracted,

which is of independent interest. Intuitively, the blockchain is a technique that maintains a public, immutable, and ordered ledger of records among all participants. It enables the participants to securely and periodically add new records into the ledger without trusting each other. It also guarantees that the records that have been added into the ledger cannot be removed or modified such that all honest participants have a consistent view of the ledger. More recently, the blockchain technique has been further investigated and one of the most prominent manifestations is to enable smart contracts. As a disruptive technique with profound implications, blockchain is transforming the very nature of how users including individuals and enterprises conduct transactions and perform smart contracts.

Generally, the blockchain technique can be classified into two types: public blockchain and private blockchain. For a public blockchain, the participants who maintain the blockchain are subject to the permissionless model, which means that anyone can join or leave the blockchain system without getting permission from a centralized or distributed authority. The most prominent manifestation of public blockchain is blockchain-based currencies, such as Bitcoin and Ethereum. The private blockchain (including the consortium blockchain) is derived from its public counterpart, where the participants who maintain the blockchain are authorized by blockchain managers or the managers themselves. At this point, the key difference between the private blockchain and distributed backup systems is that once a record is added to the blockchain, as long as the majority of participants is accessible to the adversaries, the record cannot be removed or modified, even if the blockchain manager becomes the adversary.

Foundations

Most of existing blockchain systems are either based on the proofs of work (PoW) or based on the proofs of stake (PoS) (Kiayias et al. 2017; Pass and Shi 2017; Tschorsch and Scheuermann 2016; Underwood 2016; Wood 2014). Both PoW

and PoS are key components to implement a consensus algorithm such that newly generated records can be securely added to the blockchain. PoW is a cryptographic primitive that enables a prover to demonstrate to a verifier that she/he has performed a certain amount of computational work in a specified interval of time. In the PoW-based blockchain, PoW is used to build a bridge between a user's identity and her/his hashrate, such that the more hashrate in the blockchain network, the higher probability that the content of the new block is determined by the participant. A typical PoW-based blockchain has the form shown in Fig. 1, where Block Hash denotes the hash value of current block, PreBlockHash denotes the hash value of the last block, Nonce denotes the PoW solution, Time denotes the timestamp of current block, Re denotes the record stored in the blockchain, and MerkleRoot denotes the root value of a Merkle hash tree formed by all records recorded in current block.

In the PoW-based blockchain, the participants need to solve the PoW puzzle to fight for generating the new block; this results in striking energy demands. Actually, the PoW-based blockchain has even been labeled an "environmental disaster" (Dziembowski et al. 2015). As such, a blockchain system that is constructed on another mechanism, rather than PoW, to obviate the huge energy requirements is urgently needed. Essentially, PoW in blockchain facilitates a practical randomized "leader election" process that elects one of the participants to issue the next block, where the probability to be the leader for a participant is proportional to her/his hashrate.

A natural alternative mechanism to replace PoW is the notion of "proof of stake" (PoS). In PoS-based blockchain, the probability to be the leader for a participant is proportional to her/his stake according to the current blockchain ledger. A basic observation to use such mechanism is that if the higher ratio of shareholding one has, the stronger motivation to retain the system security she/he has. A key challenge to design a PoS-based blockchain is to simulate the randomized leader election process. In most of existing PoS-based blockchain systems, this is achieved by a cryptographic protocol that participants jointly

Blockchain, Fig. 1 A typical PoW-based blockchain

Blockchain, Fig. 2 A typical PoS-based blockchain

generate a random number to elect the leader. A typical PoW-based blockchain has the form shown in Fig. 2, where Aux denotes the auxiliary information on the leader election process.

Except for PoS, some other mechanisms have been proposed to replace PoW, for example, proofs of space. In the proofs of space setting, a prover demonstrates to a verifier that she/he has significant amounts of disk space.

Applications in Wireless Networks

Blockchain-based identity management for wireless networks. Blockchain can be utilized as a database to record all users’ identities in wireless networks without a trusted authority (Garman et al. 2014). Since the blockchain is inherently resistant to forgery and modification, after the users’ identities are recorded into the blockchain, anyone cannot tamper with the identities. Compared with existing systems, the blockchain-based identity management

system does not require a trusted authority and thereby can resist the single-point-of-failure problem.

Blockchain-based random number generator for wireless networks. In wireless networks, random numbers play an important role to construct systems and protocols. In a PoW-based blockchain system, the hash value (Block Hash in Fig. 1) of each block on the chain only can be determined after a valid nonce is computed and the block is chained to the blockchain. Due to the inherent resistance against modification of blockchain, once the block is chained to the blockchain, its hash value is deterministic and would never be changed. As such, given a time t , if t is a past time, the hash value of the latest block that has appeared since t in the PoW-based blockchain is deterministic and can be extracted efficiently; if t is a future time, the hash value is unpredictable (Zhang et al. 2015, 2016). Therefore, the PoW-based blockchain can be utilized to construct a time-dependent random number generator.

Blockchain-based data sharing for wireless networks. In wireless networks, multiple network systems need to share data with each other. However, due to the differences on the data form, software version, network delay, or even node location, sharing data is always a challenging problem for different wireless network systems (Kosba et al. 2016). Since the blockchain is publicly accessible to all participants, it enables the data sharing among different systems to be feasible and efficient. Multiple systems can joint maintain a blockchain to record the data to be shared, which build bridges between these systems to share data.

Definitions

The term, “blockchain,” has various meanings in different context. It is often referred to as the set of the technologies constituting the blockchain-based system, including but not limited to the ledger, the consensus algorithm, the hash algorithm, the asymmetric cryptography, and so on (Narayanan et al. 2016). In the context of data structure, the term “blockchain” is referred to the chain of blocks. Each block includes a bundle of transactions bound together and is secured via cryptography. Each transaction is considered as connecting two entities which are identified by the cryptographic addresses generated from the public keys of them. The contents in the transaction indicate the transfer of valued data between

the involved entities. The valued data contained in each transaction can be cryptocurrency, business records, finance incoming, certificate of a care, smart contract, or anything in the digital form that is valuable. For instance, the transaction may indicate the change of the ownership of some amount of cryptographic coins from one person to another. Many transactions are combined into a block, and then this block can be added as the latest block of the chain after it is eventually validated via the kind of process named “consensus” following the rules of some certain consensus protocol. Following similar process, the subsequent blocks are appended one after another to form a growing chain, actually the blockchain, to store all the transactions that have been validated and witnessed by every single participant in the blockchain system.

The Emergence of Blockchain Technology

The relentless pursuit of the better way of payment, which is secure, anonymous, and trusted, is driven by the passion of the cypherpunk (Hughes 1997), where people advocate the spread of the usage of cryptographic technologies to the public. It is widely accepted that the first generation blockchain technology is exemplified by the decentralized cryptocurrency, among which the Bitcoin, proposed by Satoshi Nakamoto in 2008 (Nakamoto 2008), may be the first and most famous one. As the fast growth of the cryptocurrency market capitalization, the underlying technology, blockchain, is soon widely recognized by the whole world. The Ethereum, proposed by V. Buterin, G. Wood, and J. Lubin in 2014 (Wood 2014), is believed to start the era of blockchain 2.0, for it incorporates a Turing-complete language (i.e., the so-called smart contract) making it possible to implement all kinds of decentralized applications. The blockchain-based system, such as Bitcoin and Ethereum, featuring every peer freely joining in and fairly competing to add new records to the chain, is said to be “public.” In contrast, the system, like Hyperledger, where only some super recorders have the right to do

that, is regarded as the private blockchain or the consortium blockchain.

These days, blockchain supports not only the transfer of cryptocurrency in a decentralized and trusted way but also enables a wide variety of decentralized applications. It has great technological, economical, and even social significance. Everyone, to some extent, is enabled to the right to issuing private moneys via the blockchain technology, and the private money has its economic origins from the denationalization of money proposed by Friedrich Hayek in 1970s (Hayek 1990). Since the economy these days is based on the fiat, the blockchain-based cryptocurrency has the potential to change the world significantly. More importantly, it may enable new types of economic organizations and governance via smart contracts to enable the decentralized worldwide cooperation.

On the other kind, it may not only help to deal with the challenges raised by the fast development of mobile Internet and Internet of Things (IoT) but also contribute to the establishment of the future information infrastructure. Actually, some efforts have been paid into this. For instance, the MIT Connection Science Research Initiative aims at building up a future Internet architecture of trusted data (Pentland et al. 2016). In addition, Blockstack is proposed to construct a blockchain-based decentralized DNS featuring low searching latency (Ali et al. 2016).

There are also some challenges in the development of the blockchain technology and its applications that we need to deal with (Vukolić 2015; Zheng et al. 2018). The public blockchain trilemma is the trade-off between the performance, the decentralization, and the security in a blockchain-based system. At its early state, the average number of legal transactions added to the chain, proved via the Proof-of-Work (PoW) consensus protocol, is merely less than 100, while keeping good decentralization. At the cost of decentralization as well as security, the BFT protocol employed by the consortium blockchain may increase the throughput 1000 times more than the PoW protocol used by the public blockchain. The Algorand (Gilad et al. 2017), started by the

Turing award winner Silvio Micali, could be considered as a hybrid of the public blockchain and the consortium blockchain and may keep a better balance, although it is much more difficult to implement and a bit far from being used in real systems. Theoretically, the adversary may take control of the blockchain system if it holds more than one half computation resources of the PoW-based blockchain or more than one third of the BFT-based blockchain. However, in practice the computation resources that need to hold to control the blockchain system is far less than half, due to the emergence of large mining pools.

Some Critical Features of Blockchain

Some key features make it possible for the blockchain to be not only a promising ICT innovation but also an institutional technology (Aste et al. 2017; Davidson et al. 2016). Before elaborating the potential impact of the blockchain over our world, we would like to involve into the details of the blockchain itself and depict some critical features.

The blockchain-based system can be divided into the data layer, the consensus layer, the contract layer, and the application layer. The ledger is the most important data structure in the data layer. It is composed of ordered blocks which are in turn composed of validated transactions or smart contracts. The validity process, or in other words, the consensus process, is such that it ensures the chronological order in which transactions, smart contracts, and information have been created or executed, in a decentralized way. We can imagine the ordered chain of blocks as the chronicle of the history of the cyberspace, and the chronicle is composed by no means of an authority. Eliminating the central authority, every peer in the system is entitled to the access to the records in the chain. In other words, the records are traceable and transparent to every peer. As mentioned above, every peer competes to add new record, i.e., the block, to the chain, following the common consensus protocol. Once being validated and approved, the order could hardly be changed, unless the adversary takes control of big enough computation resources. In this

sense, the blockchain is considered as tamper-proof or immutable. The historic truth recorded in the chain has been validated by the whole community of peers. The smart contracts programmed based on the Turing-complete language enable the creation of decentralized applications and even the decentralized autonomous organizations which operate without human beings' involvement and without resorting to any third-party authority providing trust. To sum up, the key features of blockchain are the decentralization, the immutability, the self-execution, and the transparency.

Although one can enumerate a wide variety of areas where the blockchain technology could be applied to, we would like to elaborate the effect of the blockchain technology in a more general way. Through the public regulations coded intrinsically in the core protocol of the blockchain-based system which are transparent to all participants, it is possible to build trust between individuals and organizations in the cyberspace. Through the consensus process among the majority of the participants, it succeeds in establishing the regulations of cooperation so that the cooperation between untrusted organizations could continue. The transparency and the immutability are critical to eliminate the information asymmetry (Aboody and Lev 2000). As a result, the cost of trades and negotiations would be reduced dramatically. Also, the feature of transparency helps to break the silo of data storage in the current information management systems. It seems that the blockchain has the potential to endow the virtual cyberspace with some kind of reality and continuity. One could regard the records in the blockchain as the history of the cyberspace. Besides, some believe that blockchain is more like an innovation facilitating new types of organization and governance.

Toward the Future Internet Architecture with Built-In Security

Security Drawbacks of Current Internet Architecture

The Internet, as an information platform, has achieved a great success due to its convenience

in information dissemination. One of the key factors of this promising information platform is the efficiency and simplicity of the IP protocol in data transmission. On the other hand, the IP-based data delivery, as a kind of packet switching, has its disadvantages and drawbacks. For example, the authenticity and integrity of the transferred data can only be guaranteed by the connection that supports data transmission between the communication endpoints (e.g., a client requesting for data and a server responding with the requested data). The data can be trusted only when its provider that is connected with the requester is trusted during the data transmission. Whenever the connection is broken, the data cannot be trusted if it is retrieved from other places, even it is indeed the same with what the trusted provider supplies. In this sense, the trust is based on the connection in the current Internet. The non-repudiation of data cannot be protected by traditional Internet protocols.

Furthermore, the ownership of data in the Internet is difficult to protect after the data is uploaded into public cloud or acquired by some third-party enterprises or institutions. Whether the data is used for commercial purposes and how much business gain is achieved are not transparent to the original data owners. As a consequence, the data owners cannot benefit from any kind of data sharing although they produce and provide the data. The data abusers are not likely to get punished, which harms the data sharing in current Internet. Given the fact that the big data could be considered as the fuel for artificial intelligence, this shortcoming of the existing Internet is also detrimental to the development of advanced information technology.

Enabling Future Internet with Intrinsic Security

Fortunately, the blockchain technology is capable of enabling the current Internet with secure and trusted data storage, data access authorization, data computing, and data sharing between untrusted entities. It can provide trusted data ownership guarantee based on some consensus process between all involved Internet parties and can help virtual participants

to enable tamper-proof data or value transfer. As a result, it can help to achieve a real decentralized and secure data management in cyberspace.

Firstly, the blockchain technology can provide the consensus to claim the ownership of all scattered data stored in the Internet with cryptograph protect. If the data ownership is registered in the blockchain-based systems, it is hard for some certain third-party centralized entities to hide or abuse the data, as the data ownership can be publicly validated by all participants in any blockchain ecosystem. In the future Internet with blockchain protection on data ownership, the data of each Internet user can be stored distributed in the owner's devices or maintained by some neutral third-party data servers. Each data has its own identifier, e.g., the hash of the data. Each user also has an identifier, e.g., the public key or a bitcoin-like address of the owner of the data which is associated with the private key. The binding of the identifier of data and its corresponding owner (an Internet user) is recorded as a transaction which can only be controlled by the data owner. This binding relationship is validated by blockchain miners and then broadcast it to all the participants in this blockchain system, to reach the consensus on this data ownership. As a result, the abuse of the data is very difficult for any centralized entity since the public witness is achieved on the data ownership.

Secondly, the blockchain technology can achieve data access authorization with smart contracts, to support unified access control for different entities with different incentives. For different data with different formats or with different application functions, the blockchain provides a mechanism to generally quantify the access authorization by token incentives. Specifically, different data may have different values, which are measured with different types or number of tokens. The logic of access authorization on the data is implemented in the blockchain as smart contracts, which formulates the rules of data access and what kind of tokens and how much that requesters should pay for the data. No matter for which kind of data, the user that requests this data only need to trigger a proper smart contract on the blockchain and

transfer enough tokens to this smart contract to pay for this data. The tokens enable the unified access control for all the data in future Internet. If anyone wants to access any data, enough tokens are the only thing that should be guaranteed. That is, token is the connection bridge of every Internet user and data.

Finally, the blockchain technology can support tamper-proof records for transfer of data ownership by resorting to the immutable distributed ledgers. For every transaction in every block, the transfer of data ownership is witnessed by the public in the blockchain ledger, including the change of data ownership and the tokens that the data requester paid for. Furthermore, this transfer of data ownership is continually validated by the blockchain miners, as well as witnessed by all the participants across multiple autonomous domains. In this way, the tamper-proof records for the transfer of data ownership are confirmed in the immutable distributed ledgers by every single participant, making the transfer of data ownership trusted and verifiable.

Overall, the control of data ownership is a formidable challenge for current Internet technologies, yet the emerging blockchain technology gives a chance to solve this problem efficiently and effectively. Consequently, the blockchain technology may finally become one of the most promising candidates to achieve a future Internet with intrinsic security.

This survey focuses on privacy and security of Bluetooth Low Energy (BLE), covering the attack vectors and corresponding countermeasures.

Bluetooth Low Energy

We are approaching toward a new era of the Internet of things (IoT). Manufacturers are rushing to enrich their products with more IoT functionalities. Bluetooth Low Energy (BLE/BTLE) will act as one of the backbones for IoT wireless communication technologies. Compared with the Bluetooth Classic technology, BLE provides larger coverage area while maintaining a lower power consumption. According to the Bluetooth SIG forecast, over 90% mobile devices will support BLE by 2018 (Group 2014).

Bluetooth Low Energy (BLE) is part of Bluetooth Core Specification and is a wireless technology specifically designed to be used for novel applications in IoT. It was released in 2010 along with Bluetooth 4.0. Since then BLE 4.1, BLE 4.2, and BLE 5 (Wikipedia 2018) have been released alongside its classic counterpart.

BLE is not compatible with Bluetooth Classic. Thus, a device implementing only the low energy feature cannot communicate with a device that only implements Bluetooth Classic (Gomez et al. 2012). Other differences between BLE and Bluetooth Classic are listed in Table 1.

In the rest of this survey, we will discuss two main protocols of BLE, its privacy features, and the technical details that protect the BLE privacy. We will discuss the security issues of BLE, involving security goals and association models for secure communication. We will introduce major attacks on BLE protocols, such as DOS attack, eavesdropping, and the man-in-the-middle (MITM) attack. We will discuss vulnerabilities and design issues that cause these attacks. Finally, we will give suggestions on how to make BLE device more secure.

ATT and GATT Protocol

The ATT protocol is a client-/server-based protocol (Bluetooth 2014). The server maintains a set of attributes which can be accessed by the client once connected. Each of these attributes has a handle, a type with a universally unique identifier (UUID), a value, and a set of permissions. The handle is a 16-bit, non-zero value that is assigned by the server to uniquely index an attribute. The type is defined by UUID. Given the burden of transferring UUID values, the typical 128-bit UUID is converted to the 16-bit UUID in BLE. The UUID indicates the functionality of an attribute. Permissions restrict the accessibility of each attribute for another device, such as *read/write*, and *notify*. Table 2 is an example that demonstrates an attribute.

The GATT protocol is based on the ATT protocol and organizes attributes into *services* (Townsend et al. 2014). A service contains zero or several *characteristics*. Each characteristic contains zero or several *descriptors* as well. Characteristics are containers for user data. These descriptors are attributes that convey other information about a characteristic and its value. Services may include other services as their building blocks. The major service that contains other services is called the primary service, while the auxiliary ones are named secondary services.

Bluetooth Low Energy (BLE) Security and Privacy, Table 1 Differences between BLE and Bluetooth Classic (Wireless World 2018)

Features	Bluetooth Classic	BLE (Bluetooth Low Energy)
Range	<30 m	More than 50 m
Power consumption	30 mA	Less than 15 mA
Speed	700 Kbps	1 Mbps
Frequency channels	79 channels	40 channels (includes 37 data channels and 3 advertising channels)
Modulation	GFSK (modulation index 0.35)	GFSK (modulation index 0.5)
Latency in data transfer	100 ms	3 ms
Message size(bytes)	358 (Max)	8–47
Throughput	0.7–2.1 Mbps	Less than 0.3 Mbps
Slaves	7	Unlimited

Bluetooth Low Energy (BLE) Security and Privacy, Table 2 Attribute for Device Name

Handle	Type (UUID)	Value	Permissions
0 × 0001	Device Name (0 × 2900)	Smart Lock	Read

Secondary services must be included in primary services.

Connection Setup

There are two roles in the connection setup procedure. The client is named central device. The central device can be some smart terminals that often run on an operating systems. For example, our smartphone often plays the role of a central device. The server is named peripheral device. A peripheral device is normally a device that has specific functions, such as a smart thermometer, a smart light, or a smart lock. Sometimes, our smartphone can also be a peripheral, as long as it can provide services to some other devices. A peripheral can advertise and notify other devices that it is there. The central device responds to these advertisements with a scan request and then sets up a connection. Note that the advertisements and scan modes vary from each other (Bluetooth 2014).

We elaborate the connection setup procedure in Fig. 1.

1. The peripheral device broadcasts *advertisement* packets indicating it is connectible. These advertisement packets often contain

Bluetooth Low Energy (BLE) Security and Privacy, Fig. 1 Initial states of Bluetooth Low Energy connection

- the basic information about the device, such as the manufacturer.
2. The central device receives these advertisements and then sends a *scan* request to the peripheral to query more information about the peripheral.
 3. The peripheral device responds with a *scan response* packet that may contain more detailed information of itself, such as device name.
 4. After handling the *scan response*, the central then sends the *connect request*, if the response is in line with its expectations. The *connect request* includes the channel information that these two devices will follow during the communication.

Once a connection is established, the central device becomes the **master**, while the peripheral device becomes the **slave**. The **master** may have several **slaves** at the same time, while the **slave** can only have one **master** in 4.0 (Bluetooth 2010). This situation changes in the 4.1 (Bluetooth 2013), which allows one **slave** to have links to more than one **master** at a time.

Privacy of Bluetooth Low Energy

Privacy in BLE is an ability that avoids one device being tracked by other untrusted devices. This type of ability depends on if the device can prevent its address being decoded by other unauthorized devices. If this address gets exposed, other devices may follow the address from the advertising phase. To maintain the privacy, two devices share a secret key known as the Identity Resolving Key (IRK). The IRK is used to generate a random address that only can be resolved by the peer device who is maintaining the IRK. In the rest of this section, we will describe this process in detail.

Bluetooth Device Address

Each Bluetooth device is allocated a uniquely 48-bit Bluetooth device address (BD_ADDR). These addresses are classified as public device addresses and random device addresses. The public device address consists of two 24-bits long values, known as a company ID and a company-assigned ID. The random device address is a randomly generated address. It can be either static random address or private random address. The static random address does not change in one power cycle, while the private random address can change in one power cycle. The private random address may change at every connection. In terms of the private random address, two subtypes of addresses are included, non-resolvable private address and resolvable private address. The resolvable private address (RPA) is the foundation for privacy in BLE.

RPA Generation and Resolution

A RPA is generated from a random number (known as prand) and an Identity Resolving Key (IRK) which is shared during the pairing process. The RPA is used by one device, and only the

corresponding device that maintains the same IRK could resolve it. The format of a RPA is shown in Fig. 2.

Assume that two devices already have the IRK, respectively. To generate a resolvable private address, a device first generates a 24-bit random value (known as prand) and then passes this value with the aforementioned IRK to a hash function. The random address is concatenated by the prand and the output of this hash function, as shown in Eq. (1). Correspondingly, once another device receives this RPA, it splits it to extract the hash value and prand. Then, it performs the hash calculation as well as the first device. The RPA is resolved only when the output matches the extracted hash value.

$$Hashvalue = Hash(Prand, IRK)$$
$$RPA = Hashvalue || Prand, \quad (1)$$

Other Policies

Device filtering is a set of policies that avoid untrusted connections. It is also an effective way to reduce power consumption. There are three types of policies: advertising filter policy, scanner filter policy, and connection initiator filter policy. Suggested by their name, these policies affect different states before setting up the connection. When the policies are enabled, a device does not need to respond to every peer device, since most of the devices are filtered out. To do this, a device should maintain a white list locally, which stores the address and its type. For example, the advertising filter policy determines in which way could an advertiser process the scan/connection request. When the specific advertising filter policies are applied, devices may only allow scan/connection requests from whitelist.

The directed connectible advertisement is another way to protect the privacy of the device

Bluetooth Low Energy (BLE) Security and Privacy, Fig. 2 The format of resolvable private address

and avoid unwanted scan or connection requests. This special type of advertisement contains a RPA for the device it intends to connect to. When this type of advertisement is enabled, the device shall only share its information with the ones it wants to connect to.

Security of Bluetooth Low Energy

The application of the BLE technology will continue to grow exponentially in coming years. It also draws attackers attention at the same time. Thus, the security of BLE will have colossal importance.

The security architecture of Bluetooth has evolved over time. Initially, Bluetooth was not as secure as it is today. It could only provide weak protection for the message integrity and can be easily forged. After Version 2.1 + EDR, the Secure Simple Pairing (SSP) was introduced to mitigate the situation. This was a great revolution for Bluetooth Security. Four association models, which are practiced as of now, were also introduced at this version, known as Just Works, Numeric Comparison, Passkey Entry, and Out-Of-Band (OOB).

Along with the release of Version 4.0, the Bluetooth Special Interest Group (Bluetooth SIG) added the security model for Low Energy. However, only three types of association models were supported at this time (Just Works, Passkey Entry, and Out-Of-Band). Although they have the same name as SSP, the security provided is not the same. Some of these association models have been proved to be vulnerable.

In Version 4.1, Bluetooth SIG upgraded SSP by supporting the P-256 elliptic curve and added FIPS-approved algorithms for device authentication, which was known as Secure Connections feature. They also added message integrity by supporting AES-CCM. But they did not change the security features for the Low Energy counterpart.

It is generally acknowledged that the updates in Version 4.2 are crucial for BLE, which greatly enhances its security. At first, it added the Secure Connections feature to Low Energy,

such as upgrading the LE pairing model by supporting the AES-CMAC and P-256 elliptic curve algorithms. Secondly, it included the Numeric Comparison as a new association model in Secure Connections. Lastly, it also applied the Secure Connections features to key generation.

Security Goals

To maintain the security in Bluetooth Low Energy wireless technology, the designers must address two security goals: protection against passive eavesdropping attacks and protection against man-in-the-middle (MITM) attacks. Passive eavesdropping attacks occur when a user is communicating with the other, while an attacker is listening to their conversation stealthily without their consent. The MITM attack is a scenario where the attacker secretly emulates the partner of both communicating devices during a conversation. The attacker here has the ability to listen and change the data of that private communication.

To defend against passive eavesdropping, the traffic between two devices must be encrypted. In the earlier versions of BLE (4.0 and 4.1), the encryption is vulnerable to a brute-force attack. The Temporary Keys (TKs), which are used for further key generation and distribution, are not strong enough. However, this situation was mitigated in the newly released BLE Secure Connection. Although passive eavesdropping can be thwarted by a strong link layer encryption, the link layer encryption may be vulnerable to MITM attacks. Some association models can effectively defend against MITM attacks.

Association Models

Association models are mechanisms that determine how two devices could authenticate each other and securely exchange data with each other. In BLE, association models are used during the pairing process. As of now, there are four association models. They are Just Works, Numeric Comparison, Passkey Entry, and Out-Of-Band (OOB). Which type of the association model would be used depends on the I/O capabilities of both devices. Table 3 shows the mapping of association models according to different I/O capabil-

Bluetooth Low Energy (BLE) Security and Privacy, Table 3 How association model can be used according to different I/O capabilities

Association models \ I/O	Display	Display, Yes/No	Keyboard	No input/output	Keyboard, display
Display	Just works	Just works	Passkey entry	Just works	Just works
Keyboard only	Passkey entry	Passkey entry	Passkey entry	Just works	Passkey entry
No input/output	Just works	Just works	Just works	Just works	Just works
Keyboard, display	Passkey entry	Numeric comparison	Passkey entry	Just works	Numeric comparison

B

ities. The rows and the columns represent the I/O capabilities of two devices, respectively. Display stands for whether the device is equipped with a display, such as a screen. While keyboard stands for whether it has a keyboard. Yes/no here can be a space key, which could be used by the user to confirm or reject a value displayed on a screen.

Now we will discuss these association models in detail. We will focus whether these models could or could not cover the security goals mentioned earlier:

- **Numeric Comparison (only for LE Secure Connections):** Numeric Comparison is applicable when both devices have the capability to display and confirm information. For example, two smartphones want to pair with each other. In this association model, both devices display a six-digit number on its screen. If these two numbers are the same, they are authenticated properly. The numbers are generated from the public key of each device, a nonce, and an 8-bit code by using the AES-CMAC function. During MITM attacks, public keys of both devices will not match. As a result, the numbers displayed on each device will not match. In this way we would avoid MITM attacks effectively.
- **Just Works:** Just Works is designed for scenarios where at least one of the devices has no input/output capability. For example, a mouse and a laptop want to pair with each other. In this association model, they use the same protocol as the Numeric Comparison, but the six-digit number never shows up. Because Just

Works does not provide an interface for a user to know if the number matches, it is vulnerable to MITM attacks.

- **Passkey Entry:** Passkey Entry is designed for scenarios where one device supports entering the six-digit number (Passkey), but does not have the capability to display. For example, a keyboard and a laptop want to pair with each other. In this association model, the final confirm value is generated from the public key of both devices, a nonce and the one part of the Passkey by using AES-CMAC function.
- **Out-of-Band (OOB):** Out-of-Band is designed for scenarios where both devices possess an extra communication channel, such as WLAN or NFC, for example, two phones equipped with NFC. In this association model, the capability to defend against MITM attacks or passive eavesdropping attacks depends on what type of communication channel being used and security of that communication channel.

Pairing and Encryption

Pairing occurs when two BLE devices build a connection, which is a process used for key exchanging. Pairing involves three phases. One of the association models is used for authentication during the pairing process. Depending on the version of Bluetooth Low Energy, there are two types of pairing methods. In 4.1 and 4.0,

Bluetooth Low Energy (BLE) Security and Privacy, Fig. 3 LE legacy pairing

LE legacy pairing is used, while LE Secure Connections are supported in 4.2.

LE Legacy Pairing

We first introduce LE legacy pairing. It contains three steps, as shown in Fig. 3. In the first step, both devices exchange their I/O capabilities and security requirements, which is used to determine the association model. In the second step, the two devices determine a Temporary Key (TK) and use this to generate the Short-Term Key (STK). In the third step, a Long-Term Key (LTK) would be generated for future communications.

Determining Temporary Key (TK) TK is a 128-bit key that is used to generate the Short-Term Key (STK). Recall that three types of association models are supported to share the TK, known as Just Works, Passkey Entry, and OOB. In Just Works, the TK is always set to 0. In Passkey Entry, validated portion of TK is a random number between 000000 and 999999, while other bits can be padded with 0. Only in OOB,

the 128-bit TK can be applied. During the pairing process (Zegeye 2015), few values exchanged in plain text in the air, which can expose the TK to the attacker. These values are confirm value, devices information, pair request and response, Mrand (random value from master), and Srand (random value from slave). By knowing the *confirm value generation function* $c1$ that is defined in 4.0 (as shown in Eq. (2)), attackers could use these values to brute-force the TK in the Passkey Entry model (only 1,000,000 possibilities). Not to mention that in the Just Works model, TK is set to 0.

$$\begin{aligned}
 Mconfirm &= c1(TK, Mrand, \\
 &\quad Pairinginfo, deviceinfo) \\
 Sconfirm &= c1(TK, Srand, \\
 &\quad Pairinginfo, deviceinfo) \quad (2)
 \end{aligned}$$

Determining Short-Term Key (STK) After checking the correctness of the confirm values, devices exchange the generated random numbers (Srand and Mrand). Then the Short-Term Key (STK) is generated using the TK and random numbers (as shown in Eq. (3)).

$$STK = AES128(TK, Srand || Mrand) \quad (3)$$

Determining Long-Term Key (LTK) Devices which support encryption in the Link Layer Connection State in the slave role will generate LTK, the Encrypted Diversifier (EDIV) and 64-bit Random Number (Rand), IRK (Identity Resolving Key), and CSRK (Connection Signature Resolving Key). Among them, the LTK is used to generate session key (SK) for Link Layer Connection, while the IRK is used for random resolvable private address resolution. CSRK supports the data signing operation, which adds another security layer. A signature will be generated with the signing algorithm and a counter by using the CSRK to avoid replay attacks.

Bluetooth Low Energy (BLE) Security and Privacy,
Fig. 4 LE Secure Connections

LE Secure Connections

Compared to the LE legacy pairing, LE Secure Connections offer significantly stronger security. The TK and STK are not used. Instead, a single LTK is used to encrypt the connection, which is exchanged by using the standard (FIPS) compliant Elliptic Curve Diffie-Hellman (ECDH) public key (Sachin Gupta Rohit Kumar 2018). As shown in Fig. 4, we introduce the three steps in LE Secure Connections. In the first step, both devices settle on a certain set of domain parameters. In the second step, the two devices exchange their public keys and compute a Long-Term Key (LTK). In the third step, a set of keys are generated and distributed for future communications.

Public Key Exchange In this step, each device sends its public key to the other device (PK1 and PK2). This public key is generated from the Elliptic Curve Diffie-Hellman (ECDH). It is an effective way to thwart eavesdropping, since the

private key is never exposed in the air during the pairing.

Authentication Stage 1 To perform the authentication, one of the aforementioned association models must be used in the first authentication stage. At this stage, each device will generate a nonce (N1 and N2), which is needed to calculate a commitment (C1 and C2). Taking the Numeric Comparison as an example, the process can be described as Eq. (4). During this stage, N1 and N2 are exchanged, while the generated value D is displayed on each devices. Since there are no extra user inputs in Numeric Comparison, the user input values (ri1 and ri2) are set to 0. The Just Works model follows the same protocol as Numeric Comparison. However, Just Works is still vulnerable to the MITM attack, since there are no user interactions during the whole process. For the OOB or Passkey Entry, the process is similar. For example, in the Passkey Entry model, the ri values are not set to 0 but set to the input values of users. And the last calculation is also more complex.

$$Device1 : C1 = f(PK1, PK2, N1, ri1);$$

$$(ri1 = 0)$$

$$Device2 : C2 = f(PK1, PK2, N2, ri2);$$

$$(ri2 = 0)$$

$$D = g(PK1, PK2, N1, N2) \quad (4)$$

Authentication Stage 2 In this stage, each device collects the exchanged values to generate a Long-Term Key. Both devices will also perform DHKey (Diffie-Hellman key) check process after LTK is generated. Each side uses the DHKey as input to compute new confirmation value by using the previously exchanged information in the DHKey check process. If the check passes through on both sides, the devices start to generate the LTK. LTK is used for the link encryption and sharing keys.

Attacks on Bluetooth Low Energy

It is generally acknowledged that security in LE legacy pairing is vulnerable from many perspectives. Attackers are more likely to choose 4.1 and 4.0 BLE versions as their target as they use the legacy pairing. On the other hand, vulnerabilities can also stem from the implementation or design by any particular device manufacturer.

DoS Attack

A denial-of-service attack (DoS attack) is an attack that renders the network or computing resource unavailable to the legitimate users by disrupting the services. In BLE, the DoS attack is easy to launch and hard to defend.

In Version 4.0, the slaves can only have one master. If the master is connected to the slave, the slave will stop broadcasting the advertisement packets and will become invisible to any other devices. This makes it vulnerable to DoS attacks, since attackers could enhance their advertisement rate to win such a connection race. The situation has been mitigated in Version 4.1 as it supports the multi-master model.

The jamming attack is another DoS attack. It blocks the advertisements of a slave and makes it unconnectable. As an example, Sebastian et al. present a design of selective jammers against BLE advertising, which can block advertisements of a specific slave from being revived by other devices (Brauer et al. 2016). They theoretically prove that the selective jammer is effective and hard to detect.

Another DoS attack is known as denial-of-sleep (DoSL) attack. It can paralyze the device by draining out their battery. In this type of attack, the attackers will consume the power of the device by connecting/disconnecting with them repeatedly (Uher et al. 2016).

Passive Eavesdropping

Passive eavesdropping occurs when two devices communicate with each other and an attacker is listening to their conversation stealthily without their awareness. BLE versions 4.0 and 4.1 are subject to this type of attack, since they use the LE legacy pairing method. Specifically, for the

Just Works and the Passkey Entry of LE legacy pairing, TK is guessable, since the possibility of a TK is very limited. Since BLE uses only 40 frequency channels compared with 79 channels in Bluetooth Classic, BLE traffic is easy to follow. Manufacturers are more devoted to usability than security. Their user guides often do not mention pairing or security even if a more secure pairing method is available. Users may not use any secure pairing at all, and the BLE communication traffic will be in plaintext. Therefore, the attacker can easily deploy attacks such as command replay or injection against their products (Jasek 2016).

In 2011, Michael Ossmann released the first open-source low-cost Bluetooth test tool, named Ubertooth One (Ossmann 2011). In 2013, Mike Ryan built a BLE sniffer over Ubertooth and explored the vulnerability in the LE legacy pairing. A tool called *Crackle* was released at that time to attack Just Works and the legacy Passkey Entry pairing methods (Ryan et al. 2013) of BLE 4.0 and 4.1. In 2014, The Adafruit Bluefruit LE sniffer was introduced Townsend (2014). The Passkey Entry pairing method in BLE 4.2 is secure with a new passkey exchange protocol.

MITM Attack

The MITM attack brings havoc to the BLE protocol. In a MITM attack, the attacker pretends to be a one device (a slave or a master), intercepts the connection from the its peer device, and then relays messages between the two original communicating parties. The Just Works pairing method of any version of BLE suffers from this attack. For example, for LE Secure Connections, Just Works does not check if the six-digit confirm number matches, mostly because there is no I/O such as a display on the devices. Sometimes, even if a victim device has necessary IO capabilities, an attacker could trick them force to use the Just Works. For example, an attacker impersonates as one device and tells the other device that it has no I/O capability. As a result, the only choice is the Just Works pairing method. Therefore, the MITM attack can then be launched (Haataja and Hypponen 2008).

The spoofing attack is a special type of MITM attack or can be regarded as a building block

of the MITM attack. The attacker pretends to be a legitimate device and communicates with the target collecting sensitive information, such as password. That is, in a spoofing attack, the attacker does not relay messages, but pretends to be the slave of interest communicating with the master. Numeric Comparison (only for LE Secure Connections) and Passkey Entry could avoid this type of attack. The OOB pairing can defeat the MITM attack if the OOB channel is secure.

To perform a MITM attack, an attacker needs two role players (i.e., two BLE devices), a DoS attacker and a fake service provider. The DoS attacker blocks the communication between the master and the slave, while the fake service provider forges a fake Bluetooth MAC address that is the same as the victim slave's MAC address, fake advertisements, and fake services. To know all such information, the attacker has to perform sniffing and reverse engineer the applications and even the target hardware sometimes.

Attacks Against BLE Apps

Given the extra cost (such as a display or a Wi-Fi adapter) of using more secure association models and convenience, BLE device designers may prefer to use Just Works. As we know, Just Works is subject to the MITM attack. To address this, the developers of the smart device can implement extra security mechanisms on the application layer, such as password-based or challenge-response authentication.

We now discuss design pitfalls of the application layer security mechanisms.

Mis-Bonding (or Co-located attack in the context of BLE) Under the context of Bluetooth-enabled smartphones, Mis-Bonding refers to the problem that an unauthorized app can access the sensitive user data on the smart device. The data was only designed for the official app initially. Because of vulnerabilities existing in the smartphone's permission mechanism, the data becomes accessible for all apps, even a malicious one. In this case, a malicious app could stealthily gather the data of a device that paired with the smartphone like an official app and then fed the

data to a remote malicious server (Naveed et al. 2014). Because this is a vulnerability in application layer, the link layer encryption is useless in this case.

Password authentication Many BLE-enabled devices use the password authentication. The implementation is often problematic.

- **Clear-text data transformation:** Passwords transmitted in plaintext can be captured through passive eavesdropping.
- **Unlimited login attempts:** This allows the attacker to launch a brute-force attack. However, there is a trade-off if the number of login attempts is limited. Limiting login attempts allows the attacker to perform DoS attacks.
- **Small password space:** Many devices only support six-digit passwords, since a complex and long password may reduce usability. This makes the devices suffer from brute-force attacks. Designers use specific a hash function or an encoding function to make up the shortness, but finally proved to provide few valid mitigations for this. Attacker can also use multipliable devices in parallel to perform an off-line brute-force attack.

Bluetooth Low Energy v.s. Bluetooth Classic

In Dunning (2010), John Paul et al. summarized the basic attacks in Bluetooth Classic. We add new attacks into the table and try to identify the difference between BLE attacks and attacks against Bluetooth Classic. As shown in Table 4, most attacks against Bluetooth Classic are also threats against BLE.

Defense Measures

Based on the discussion in this paper, we present guidelines for BLE security as follows.

- **Prevent advertisement abuse:** Do not put any sensitive information into broadcast packets.

Bluetooth Low Energy (BLE) Security and Privacy, Table 4 Bluetooth Classic attacks vs. these in BLE

Attack classification	attack description	Threat level	Examples	If exists in BLE
Surveillance	Gather user information (not privacy)	Low	Blueprinting (tsb 2017a)	Y
Range extension	Extend the attack range	Low	BlueSniping (tsb 2017c)	Y
Obfuscation	Hide attacker's identity	Low	bdaddr (Whigu 2018)	Y
Fuzzer	Submit nonstandard input to achieve malicious result	Medium	BlueSmack (tsb 2017b)	Y (Sullivan 2015)
Sniffing	Passive eavesdropping	Medium	FTS4BT (fte 2018)	Y
DoS	Block the services	Medium	Signal jamming (Köppel 2013)	Y
Brute-force address	Brute-force the address of devices to trace connection	Medium	Address exhaustion (altCross et al. (2007))	Y
Brute force in pairing	Brute force in the temporary key or PIN during the pairing	High	btpincrack (Project 2017)	Y
Mis-Bonding	Unauthorized app can access the sensitive data from smartphone	High	DMB (Naveed et al. 2014)	Y
Relay attack	With the help of relay device, implement unwanted unlock	High	Home lock attack (Ho et al. 2016)	Y
MITM	Attacker mask itself as parter to achieve malicious result	High	bthidproxy (Mishra 2012)	Y
Malware	Malwares that propagated through Bluetooth	High	CommWarrior (Wei et al. 2008)	Y
Unauthorized access	Control the smartphone and steal sensitive data	High	Car Whisperer (tsb 2017d)	Y

- **Enforce the user to pair:** This is an effective way to thwart the passive eavesdropping.
- **Use version 4.2 and above:** BLE 4.1 and 4.0 suffer from the TK brute-force attack.
- **Do not use the Just Works if possible:** Just Works is vulnerable to MITM attacks, even in BLE 4.2.
- **Implement encryption in application layer** Designers should not invent their own cryptographic algorithms and protocols if there are well-known ones that can do the job. Encryption should be adopted to prevent passive monitoring data leaks.
- **Strengthen the password authentication:** Increasing the password space and limiting the login attempts are the most straightforward but effective ways to strengthen password authentication, and the communication should be encrypted.
- **Protect source code carefully:** It can be seen that a lot of attacks can be launched partially because attackers are able to reverse engineer the BLE apps (Cyr et al. [2014](#); Rieck [2016](#); Allan and Mistry. [2014](#)). Therefore, obfuscation, JNI, code encryption, and other methods should be applied to protect source code.
- **Implement OTA (over-the-air) capabilities into each device:** Enough space should be allocated in the device memory so that code can be updated to patch holes.

Conclusion

This survey focuses on privacy and security of Bluetooth Low Energy (BLE), covering the attack vectors and corresponding countermeasures. Given the vulnerabilities in BLE 4.0 and

4.1, we highly recommend that BLE 4.2 and 5 should be adopted whenever possible. The Just Works pairing strategy in all BLE versions are subject to MITM attacks. It should not be used. In case that Just Works has to be used because of cost and usability issues, application level encryption and authentication is recommended.

Definition

Brain-machine interfaces (BMIs) refer to communication systems between the brain and an external device. Desired properties of BMIs include bidirectionality, high spatial and temporal resolution, low invasiveness, accuracy, and robustness. In this paper, the different types of BMIs, the state of the art, and the

future directions are discussed, in addition to highlighting their key applications.

Historical Background

For many decades, the interaction between humans and machines has been restricted to the exchange of visual, auditory, and tactile information. A conceptual analysis of the existing human-machine interfaces (HMI) reveals that the amount of useful information that can be exchanged between humans and machines is not limited by the capabilities of the human brain or those of the machine processor, but by the interfaces between them. Simply stated, from an engineering perspective, the human being can be modeled as a *macro-system* with a processing powerhouse, i.e., the brain, and a collection of peripherals, i.e., the sense organs. All the peripherals have their own latency limitations, which mainly arise from the fact that they convert a collection of *nano-/micro-events*, i.e., neuronal activity in the form of action potential signals, into a *macro-sized effect*, e.g., moving the fingers to touch a display or type some characters in order to control an external machine or, reciprocally, convert a macro-size effects, e.g., an auditive or visual command, into a collection of nano-/micro-events in the brain.

In order to overcome the limitations of the peripheral system, direct communication with the brain is needed. This form of interaction is known as a brain-machine interface (BMI). Over the years, numerous applications have resulted from these two-way interactions, where compensations are made between the computational capabilities of both systems. Such compensations can be in the form of either the computing system analyzing the brain signals and adapting the computing environment or the computing system providing added computing power to compensate for shortcomings of the brain. In the first case, brain signals are used to understand the user's context which is then used to control machines, such as controlling the vehicle. In the second case, this could come in the form of computing systems

controlling neuroprosthetic devices for disabled patients.

Electrical Brain-Machine Interfaces

The most common to date BMIs rely on the collection and excitation of electrical signals from the brain. Electroencephalogram (EEG) signals have been successfully utilized to directly control machines without the need of the sense organs (Millan et al. 2004). EEG signals can be collected in a noninvasive way, i.e., from outside the brain, and support high-temporal resolution, i.e., down to the sub-millisecond scale, but have limited spatial resolution, i.e., cannot be utilized to read the action potential signal from a single neuron at a time, and are vulnerable to electrical artifact sources. Besides EEG-based BMIs, there are other more invasive mechanisms that could be utilized to enable more robust electrical BMIs, such as intracranial EEG (Leuthardt et al. 2006), which is also known as electrocorticogram, and microelectrode arrays, which are placed directly on the exposed surface of the brain (Hochberg et al. 2006). However, besides their invasiveness, they suffer from several limitations, such as complex application or unsuitability for long-term use.

Optical Brain-Machine Interfaces

In parallel to the development of the aforementioned approaches, the field of optogenetics, i.e., the use of light to interact with genetically modified neurons in the brain (Zemelman et al. 2002; Deisseroth 2011; Zhang et al. 2007), has experienced a major revolution in the last decade. Optical neural stimulation is considered to be more beneficial than electrical neural stimulation, because it permits activation or inhibition of specific types of neurons with sub-millisecond temporal precision and eliminates electrical artifacts. Current approaches to optogenetic neural interfaces include the use of optical fibers coupled to lasers or light-emitting diodes (LEDs) (Zorzos

et al. 2010) and micro-LED arrays (McGovern et al. 2010). Moreover, optogenetics enables bidirectional interfaces, as light can be utilized both to control and to measure neuronal activity (Kwon et al. 2014). However, the size of existing optical devices makes them invasive, difficult to contact to individual neurons, and, ultimately, not suitable for chronic BMIs (Marblestone et al. 2013).

Wireless Brain-Machine Interfaces

In order to overcome the limitations of traditional electrical and optical BMIs, wireless BMIs are being developed. In Seo et al. (2013), the concept of neural dust was introduced for the first time. In the envision architecture, miniature electronic devices or dust motes are implanted in the cortex. These devices, which integrate piezoelectric energy harvesting systems powered by ultrasounds, record the neural activity from the cortex and transmit the information to a subdural transceiver mounted under the skull. This device is in charge of controlling the neural dust and to communicate with the external head-mounted transceiver, where the data is collected. Despite the advantages of this wireless architecture, the fact that it relies on the principles of electrical BMIs limits its applications.

Recently, in Wirdatmadja et al. (2017), the first wireless BMI based on wireless optogenetic nanonetworking devices (WiOptNDs) was proposed (Fig. 1). WiOptND enables accurate, robust, high-throughput, and minimally invasive BMIs by leveraging the state of the art in nanophotonics, nanoelectronics, and wireless communication. The fundamental idea is to replace existing micro-LED arrays and micro-photodetector arrays used in optical BMIs by a network of coordinated nano-devices, which are able both to excite individual neurons and to measure their activity. In this application, a network of collaborative WiOptNDs is utilized both to excite multiple neurons according to incoming commands and to collect, process, and transmit accurate neuronal activity in real time.

Brain-Machine Interfaces, Fig. 1 The WiOptND architecture consists of (i) a network of coordinated nano-devices able to optogenetically excite and measure the response of neurons; (ii) an intermediate transceiver in charge of both controlling the nano-devices in order

to generate different neuron excitation patterns as well as acoustically powering them; and (iii) an external transceiver in charge of acoustically powering the intermediate transceiver and interfacing it with the actual BMI user

Each nano-device is equipped with an optical nano-transceiver (Feng et al. 2014) and nano-antenna (Nafari and Jornet 2017), which is able to both emit and detect optical radiation at a pre-established frequency or wavelength. As in Seo et al. (2013), WiOptNDs are acoustically powered and remotely controlled through the subdural transceiver (Fig. 1).

Many benefits in this approach exist. First, the very small size of optical nano-antennas (Dorf-muller et al. 2010; Nafari and Jornet 2017), below 1 micrometer in the largest dimension, enables the possibility to measure the neuronal activity in a single neuron, with very high accuracy. Moreover, the total size of each individual nano-device, up to a few cubic micrometers at most (Akyildiz and Jornet 2010), minimizes the invasiveness of this approach when compared to

existing optogenetic approaches, which require bulky lasers or optical fibers. Moreover, by operating at optical frequencies, much higher temporal resolution than traditional electrical BMIs can be achieved. For example, while the main features of action potential signals are in the millisecond scale, the possibility to measure those signals with much higher temporal resolution, such as a few microseconds or even less, may unveil new high-frequency time transients in the action potential signal propagation, which could shine new light into the exploration of neuronal pathways. This also enables potentially much faster BMIs. For the time being, however, electrical and optogenetic BMIs are at an early stage, in which some of the system components have been developed and tested, but a fully functional BMI has not been realized.

Future Directions

To enable practical long-term implantable wireless BMIs, there are several bottlenecks that need to be overcome.

- From the *hardware perspective*, the major challenges are in terms of the miniaturization of the neural dust motes. Nano-lasers, nano-antennas, and nano-photodetectors are needed to excite and monitor neural activity through optogenetics. For the time being, the smallest laser, experimentally demonstrated to date (Feng et al. 2014), is a micro-ring laser with 10 μm in diameter. Given the average size of a neuron cell body, tens of micrometers, current nano-lasers should be able to achieve single neuron resolution, provided that they are near it (otherwise, light spreading would result into the illumination of multiple neurons). Optical nano-antennas can be utilized to then overcome this problem. Besides the optics, piezoelectric energy harvesting nano-systems (Wang 2008; Wang et al. 2017) and minimal computational and data storage capabilities are needed.
- From the *communications perspective*, effective communication protocols to operate the WiOptNDs are needed. Addressing of individual nano-devices, precise triggering of the optical stimulation, and accurate collection of information are crucial tasks to be performed reliably and with energy efficiency in mind. When developing such protocols, the physics of the intra-body channel, which affects the propagation of optical signals for optogenetic excitation and measurement (Wirdatmadja et al. 2018) as well as of the acoustic signals required to power the nano-devices (Donohoe et al. 2016), need to be taken into account. As important as their impact on the signal power, their impact on time distortion and synchronization needs to be studied (Noel et al. 2018).
- In all cases, *human factors* need to be taken into account. For the time being, the advanced BMIs (i.e., anything beyond EEG signal col-

lection from over the skull) have been primarily tested in vitro cell cultures or animals. One of the promising approaches relies on the use of cerebral organoids, i.e., artificially grown, in vitro, miniature organs resembling the brain. These organoids reproduce the exact behavior of the brain and are the basis of recent breakthroughs in neuroscience (Stachowiak et al. 2017). Beyond in vitro testing, the implantation of the devices needs to be optimized. Beyond surgery, the combination of nasal injection and self-assembly techniques for nano-devices is being considered.

Key Applications

- BMIs can significantly improve the quality of life of people with disabilities, by providing them a transformative way to interact with the environment and restoring functional abilities and even cognition. For example, the direct control of machines from the brain can help to overcome the limitations in the “interfaces” between them, namely, the sensor organs or locomotion apparatus.
- BMIs can help to broaden the understanding of the developmental- and aging-related diseases, such as schizophrenia or Alzheimer, whose origin lies at communication problems between consecutive neurons, and, ultimately, enable transformative treatments.
- BMIs can help to control specific types of neurological disorders, which to date have been a major challenge. A good example is epilepsy. The development toward using miniaturized neural dust motes that can be implanted deep into the brain, coupled with optogenetics, can provide a mechanism of controlling neurons at a single cell level. This means that by understanding the source of the epilepsy, controls can be developed to suppress the seizure signaling.
- BMIs can help to augment people’s brain power going into the future. New concepts such as *Targeted Neuroplasticity Training* can emerge, whereby the computing power capa-

bilities are augmented with the brain's training process. This could enhance the brain with new skills and also provide people the abilities to acquire new skills where they previously lacked.

Brownian Motion

Mohammad Upal Mahfuz

Richard J. Resch School of Engineering,
University of Wisconsin-Green Bay, Green Bay,
WI, USA

Synonyms

Diffusion; Molecular propagation; Random motion; Random walk; Thermal excitation of molecules

Definition

Brownian motion is the random motion of particles, e.g., molecules, suspended in the fluid medium, e.g., liquid and gas, that results from a large number of collisions those particles experience with the fast-moving particles of the fluid medium.

Acronyms

BM	Brownian motion
MC	Molecular communication
MRBP	Molecule-receptor binding process
RN	Receiving nanomachine
TN	Transmitting nanomachine
VRV	Virtual reception volume

Historical Background

Brownian motion (BM) is an important phenomenon that is the basis of diffusion-based propagation of molecules in molecular communication (MC) and, therefore, is the fundamental principle behind diffusion-based MC in the field of nanoscale communication networks, also known as nanonetworks. In the field of natural and applied sciences, BM is also popularly known as random walk motion of particles. The history of BM is quite old.

Random walk motion of particles was first observed by Scottish botanist Robert Brown (1773–1858) who found with a microscope that pollen particles jiggled at a very high speed while they were suspended in water medium (Brown 1828) and hence the name Brownian motion. However, it was Albert Einstein who explained BM with the theory that it is due to an extremely large number of collisions that particles under investigation experience by interacting with the particles of the fluid medium (Einstein 1905). In the field of nanoscale communication networks (Akyildiz et al. 2008; Bush 2010), the concept of BM received a huge amount of interest among researchers (Ahmadzadeh et al. 2017, 2018; Eckford 2007; Gohari et al. 2016; Haselmayr et al. 2017; Jamali et al. 2018; Kadloor et al. 2012; Koo et al. 2016; Nakano et al. 2012, 2013, 2014; Pierobon and Akyildiz 2010, 2011) who referred to the theory of BM as the fundamental principle of the diffusion process (Berg 1993) to investigate the performance of MC systems among nanomachines. Thus, MC based on BM was considered as an option for communications among nanomachines forming nanonetworks (Akyildiz et al. 2008). Some of the works in this field later contributed to the knowledge base while developing the standards for nanoscale communication networks (IEEE 2016).

Foundations

Physical Process

Random walk motion is the fundamental principle of BM. When molecules are suspended in a fluid medium, due to thermal excitation, the molecules collide with one another and thus they propagate in three dimensions (Berg 1993). Such movements of molecules could be either in a truly random direction when there is no external force present in the system or towards a given direction determined by the presence of an external force in the system (Berg 1993). The collisions between molecules occur on a very tiny timescale on the scale of picoseconds (Höfling and Franosch 2013), and thus billions of such collisions can take place within a small

duration of time. When all the factors that can impact the movement of molecules are considered absent, these collisions are truly random and, therefore, molecules undergo diffusion process (Berg 1993; Berg and Purcell 1977; Crank 1975; Einstein 1905) and thus move in a random direction in the fluid (propagation) medium. Random walk of molecules can be characterized by the two major types, namely, continuous-time and discrete-time random walks, distinguished by the step size of the particle between two states and the time the particle remains in one state before it moves to the next state (Metzler and Klafter 2000).

Normal diffusion process is based on uncorrelated random walk model of the movement of the molecule in the fluid medium where the direction of the new movement of the molecule is independent of the direction of its previous movements and can be equally likely in any of the directions in the three-dimensional space. On contrary, anomalous diffusion is based on correlated random walk model of the molecule in the fluid medium where the next movement of the molecule is likely to continue in the current direction (Mahfuz et al. 2016). In the field of MC and nanonetworks, while most researchers have considered normal diffusion process as a result of random walk motion of molecules between a transmitting nanomachine (TN) and a receiving nanomachine (RN), a few researchers have considered anomalous diffusion of molecules and presented investigative results in the aspects of MC systems (Cao et al. 2015; Mahfuz et al. 2016; Mai et al. 2017). While normal diffusion considers random BM of molecules between TN and RN, anomalous diffusion considers the abnormalities involved in the normal diffusion process, for instance, when information molecules are confined within a small space, e.g., intra-cellular space, or when information molecules (particles) interact with one another, e.g., charged particles (Mahfuz et al. 2016). Current literature has also investigated into the role of anomalous diffusion on molecular propagation and availability of molecules at the RN as well as the performance of MC receivers (Cao et al. 2015; Mahfuz et al. 2016; Mai et al. 2017).

Molecular Propagation and Communication

BM is the fundamental principle that is the basis of molecular propagation between a pair of nanomachines in diffusion-based MC systems. As shown in Fig. 1, in the aspects of MC, when a TN, located at the origin (0,0,0) of the axes, emits information-carrying molecules in the fluid medium, these information-carrying molecules experience BM and, after a huge number of collisions with the molecules of the fluid medium, finally reach an RN located at (x,y,z) . As shown in the inset in Fig. 1, the RN is located in the center of a small virtual reception volume (VRV) (Atakan and Akan 2010), which is a small unit volume surrounding the RN where the RN can sense information-carrying molecules, shown as blue circles, that become available to RN and come into contact with the receptors on its surface. Although information molecules can bind with the surface receptors with some probability as governed by the molecule-receptor binding process (MRBP), when a sufficiently large number of surface receptors are assumed, this ensures that the available information molecules at the RN come into contact with the RN and be received by the RN. Thus, the RN receives the information molecules and detects the message by processing the received information-carrying molecules. Here, the RN is assumed to be a transparent receiver that does not affect the BM of the information molecules in the fluid medium. RN is also assumed to perfectly count the number of information molecules that become available within the VRV at a given time.

In the three-dimensional propagation medium denoted by x , y , and z axes, these information-carrying molecules propagate independently in three dimensions and reach the RN located at a distance r from the TN, where $r^2 = x^2 + y^2 + z^2$. The diffusion of information molecules in three dimensions and time (t), in second (s), can be expressed as Eq. (1) below (Berg 1993)

$$\frac{\partial U}{\partial t} = D \nabla^2 U \quad (1)$$

Brownian Motion, Fig. 1 Diffusion of information-carrying molecules in three dimensions in the unbounded propagation medium (Mahfuz et al. 2014)

where U denotes the concentration of information-carrying molecules, i.e., the number of information-carrying molecules per unit volume of reception space, D (in $\mu\text{m}^2/\text{s}$) denotes the diffusion coefficient of information molecules propagating in the given fluid medium, and $\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$. The value of D is given by $D = \frac{k_B T}{6\pi\eta R_H}$ where $k_B = 1.38 \times 10^{-23}$ J/K is the Boltzman constant, T is the temperature (in K), η is the viscosity of the fluid medium, and R_H is the hydraulic radius of the molecule (Nakano et al. 2013). Diffusion coefficient values of commonly used information molecules can be found in Nakano et al. (2013) and Freitas (1999). Often, it is necessary to measure the values of diffusion coefficient experimentally for which there have been several methods to follow. For instance, several static and dynamic methods to obtain diffusion coefficient values experimentally have been explored in Culbertson et al. (2002). A simple and inexpensive experimental method to measure diffusion coefficient when temperature and pressure vary has been shown in Delgado et al. (2005).

When the TN located at (0,0,0) is assumed to transmit Q_0 molecules, all at a time in an impulsive manner at time $t = 0$, the average concentration of information-carrying molecules, in number of information-carrying molecules per unit volume of the reception space, available at the RN, located at (x, y, z) in an unbounded three-dimensional propagation medium, can be found from the solutions of the diffusion equation in Eq. (1) as follows (Berg 1993):

$$U(r, t) = \frac{Q_0}{(4\pi Dt)^{3/2}} \exp \frac{-r^2}{4Dt} \quad (2)$$

For the transparent receiver mentioned earlier, Eq. (2) shows the average number of information-carrying molecules per unit volume, i.e., concentration of information-carrying molecules, for a given number of transmitted molecules, Q_0 . The concentration of information-carrying molecules $U(r, t)$ depends on distance (r) to the RN and the time elapsed after the release of the molecules from the TN. Apart from the transparent receiver

mentioned in this entry, for other types of MC receivers, interested readers are referred to the following entry of this book: “► [Receiver Mechanisms for Synthetic Molecular Communication Systems with Diffusion](#)” by Ahmadzadeh, A., Jamali, V., Wicke, W., and Schober, R.

There are several simulation frameworks currently available that help researchers to simulate BM in the study of MC-based nanonetworks. For instance, N3Sim uses diffusion-based MC to provide a simulation framework for nanonetworks with transmitters, receivers, and harvesters (Llatser et al. 2014). N3Sim not only uses BM dynamics to model the movements of molecules but also includes inertia of and interaction among the molecules in the system. Another simulation framework named AcCoRD (Actor-based Communication via Reaction Diffusion), which is an open-source project written in C programming language, is designed and used for MC analysis and reaction diffusion solutions (Noel et al. 2017). NanoNS, built on the widely used network simulator NS-2, is another simulation framework that simulates the diffusion-based MC in nanonetworks (Gul et al. 2010). To simulate the behavior of diffusion-based MC with drift effect inside blood vessels, a software simulation platform named BiNS2 has also been introduced (Felicetti et al. 2013).

Key Applications

The applications of BM include all scenarios where particle movement is used. One of the notable applications of BM would be in the diffusion-based MC and nanonetworks fields, for instance, in drug delivery and disease treatment as well as environmental monitoring, protection, and control (Akyildiz et al. 2008; Nakano et al. 2013).

Budget Feasibility

► Budget Feasible Mechanisms

Budget Feasible Mechanisms

Hamed Shah-Mansouri and Vincent W. S. Wong
Department of Electrical and Computer Engineering, The University of British Columbia, Vancouver, BC, Canada

Synonyms

[Budget feasibility](#); [Combinatorial auctions](#); [Incentive compatibility](#)

Definitions

Budget feasible mechanisms refer to procurement combinatorial auctions in which the auctioneer with a limited budget chooses a subset of items with the goal of maximizing its valuation.

Background

Mobile and wireless systems are evolving at a rapid pace due to the tremendous growth of data traffic. The exceedingly large number of devices and the emergence of new applications and services make the design and management of wireless systems even more challenging. However, traditional models are not capable of supporting future systems such as fifth generation wireless

networks and Internet of Things (Wong et al. 2017).

Auction theory is an applied branch of mathematics and is promising for design, management, and economic analysis of wireless systems. Auction theory is widely applied in different areas of mobile and wireless systems including mobile crowdsensing (e.g., Shah-Mansouri and Wong 2015; Song et al. 2017), spectrum sharing (e.g., Huang et al. 2006; Niyato et al. 2009; Wu and Vaidya 2013), radio resource allocation (e.g., Zhang et al. 2013), multiple access management (e.g., Akkarajitsakul et al. 2011), device-to-device communication (e.g., Xu et al. 2013), and virtualization of fifth generation wireless networks (e.g., Zhu and Hossain 2016).

Auction Mechanisms

Auction is a process to buy and sell commodities and services and is characterized by a set of rules determined by an intermediate agent who manages the auction process. This agent is referred as the auctioneer. Auctions are modeled as interactions among buyers/sellers and the auctioneer. Auction commodities are exchanged based on submitting bids and asks to the auctioneer and receiving payments according to the auction rules. Buyers (sellers) submit their bids (asks) for the commodities and services to the auctioneer. The auctioneer either accepts the bids (asks) or rejects them and clears the market based on the auction rules. There are different types of auction designs. The auction mechanisms can be categorized into the following types based on the role of buyers and sellers.

- *Forward auctions*: The buyers request to obtain the commodities and services from sellers by submitting increasingly higher bids.
- *Reverse auctions*: The sellers compete to offer their commodities and services to buyers by submitting decreasingly lower asks.

Auctions can also be categorized into single-sided and double-sided as follows:

- *Single-sided auctions*: In a single-sided auction, only buyers or sellers submit their bids or asks to the auctioneer.
- *Double-sided auctions*: In a double-sided auction, both buyers and sellers participate in market interactions by submitting their bids and asks.

Other types of auctions are studied by Krishna (2009). Auctions are composed of two major components, which are the winner determination and payment schemes. The winner determination scheme selects a subset of participating players as the winners of the auction. The payment scheme determines the clearing price of commodities and services exchanged during the auction.

Incentive Compatibility

Auction is a powerful tool to model and manage the market of exchanging commodities and services. However, strategic behavior of players may degrade the auction's outcome. Selfish players may misreport the true cost or valuation of their commodities and services in order to gain higher payoffs. For example, a seller may ask for a price higher than the cost associated with its services. Incentive compatibility, which is also referred as truthfulness, is an important property of auctions. An auction mechanism is incentive compatible if reporting the true cost or valuation is the dominant strategy of the players. That is, a player cannot achieve a higher payoff by deviating from the true cost or valuation regardless of other players' strategies. To be immune against the strategic behavior of selfish players, an auction mechanism should be incentive compatible. To achieve incentive compatibility, as shown by Nisan et al. (2007), the winner determination scheme should be monotone, and the payment scheme should be based on critical payments. In a reverse auction, the monotonicity of the winner determination scheme means that if a bidder can win the auction with a certain bid, it can also win the auction with any lower bids. Moreover, the critical payment is the highest bid that the bidder can submit and win the auction.

Utilizing the critical payments is necessary to achieve incentive compatibility. This however may require a large amount of payment. The Vickrey-Clarke-Groves (VCG) mechanism, which is a well-known auction mechanism, may impose an unbounded payment to achieve incentive compatibility (Vickrey 1961; Krishna 2009). This essentially prevents the auctioneer to design a budget feasible mechanism based on VCG. Moreover, the VCG mechanism allocates the items in a socially optimal manner. However, since the budget feasible mechanisms are involved with combinatorial optimization, the VCG mechanism becomes computationally inefficient to manage large markets.

Combinatorial Auctions

Combinatorial auctions refer to a type of market where discrete items are exchanged, and the buyers (sellers) can place bids (asks) on combinations of these items. A survey of combinatorial auctions is provided by De Vries and Vohra (2003). Combinatorial auctions are widely used to model and manage the wireless systems due to the discrete nature of resources and services. Combinatorial auctions are more complex than those auctions which are only involved with commodities of continuous quantity. Due to the computational complexity of combinatorial auctions to achieve an optimal allocation of commodities, several algorithms have been introduced to find sub-optimal allocations. A combinatorial auction is computationally efficient if it can clear the market in polynomial time. In other words, if both winner determination and payment schemes can be terminated in polynomial time, the auction is efficient. Moreover, to quantify how good a sub-optimal allocation, the approximation ratio is investigated. The approximation ratio is the ratio between the optimal outcome (e.g., services' valuation) of the auction and the outcome obtained by an approximate algorithm.

Budget Feasible Mechanisms

Budget feasible mechanisms refer to procurement auctions in which the total payment does

Budget Feasible Mechanisms, Table 1 Comparison of budget feasible mechanisms and their approximation ratios for large-scale systems

Mechanism	Approximation ratio
Singer (2010)	117.7
Chen et al. (2011)	$\frac{5e}{e-1} \approx 7.91$
Song et al. (2017)	$\frac{2e}{e-1} \approx 3.16$

not exceed a limited budget. From now on, this article focuses on a single-sided reverse auction mechanism where the auctioneer with a limited budget chooses a subset of items. The objective of the auctioneer is to maximize its valuation while satisfying budget feasibility. On the other hand, each seller submits a bid in order to maximize its payoff, which is the payment received from the auctioneer minus the cost. Different budget feasible mechanisms have been proposed in the literature as listed in Table 1.

Singer (2010) proposed an incentive compatible budget feasible mechanism for general submodular valuation functions as an important class of set functions. In this mechanism, the auctioneer aims to maximize the valuation function by selecting a subset of items. Since maximizing a submodular function under a budget constraint is known to be NP-hard, a greedy-based approximation method is proposed. To derive the winner determination scheme, a valuation maximization problem is formulated when the payments are substituted by the bids and the auctioneer spends a fixed fraction of the budget. The items are greedily selected based on their marginal contribution to the valuation function in order to achieve a computationally efficient but approximate solution. The payment to each bidder is then determined based on the critical payment. Singer (2010) first showed that such budget feasible mechanism is incentive compatible. He further derived an upper bound on the approximation ratio of the mechanism by showing that for any submodular functions, the ratio between the valuation obtained by an optimal mechanism and that of the proposed greedy-based mechanism is no larger than 117.7.

Chen et al. (2011) further analyzed the aforementioned budget feasible mechanism and pro-

vided a tight bound on the approximation ratio of the greedy-based mechanism. They showed that for any submodular functions, the approximation ratio is less than or equal to $\frac{5e}{e-1} \approx 7.91$.

Song et al. (2017) also proposed an incentive compatible budget feasible mechanism for general submodular functions and applied the mechanism to a mobile crowdsensing system to model the market. Inspired by Singer (2010), a valuation maximization problem is formulated when the payments are substituted by the bids. Singer (2010) used a constant fraction of the budget to determine the winners. However, Song et al. (2017) determined the required fraction of budget based on the market dynamics (e.g., the bids and the valuation function). The required fraction of budget to achieve incentive compatibility essentially depends on the bids submitted by winners, which are not known *a priori*. Song et al. (2017) employed an adaptive approach and iteratively updated the amount of spent budget when determining the winners. They analyzed the approximation ratio of their proposed budget feasible mechanism and showed that it always outperforms the mechanisms proposed by Singer (2010) and Chen et al. (2011). They further showed that when the number of winners tends to infinity, the approximation ratio approaches $\frac{2e}{e-1} \approx 3.16$. This illustrates the applicability of the budget feasible mechanism proposed by Song et al. (2017) for large-scale systems such as mobile crowdsensing.

In addition to the budget feasible mechanisms presented in Table 1, there are several other incentive mechanisms in the literature. Although they achieve incentive compatibility and budget feasibility, they do not provide the approximation ratio of their sub-optimal allocation mechanism in general cases. Anari et al. (2014) analyzed the budget feasible mechanism proposed by Chen et al. (2011) for large-scale crowdsensing systems and proved that the approximation ratio approaches $1 - 1/e$ in this case. Zhao et al. (2016) proposed an online budget feasible mechanism for mobile crowdsensing systems. They further showed that the ratio between the social welfare obtained by their proposed online mechanism and

optimal social welfare of an offline mechanism is constant. Furthermore, Dobzinski et al. (2011) proposed a budget feasible mechanism for more general valuation functions. They showed that for a market with n participants, the approximation ratio of the sub-optimal allocation is $O(\log^2 n)$ for sub-additive valuation functions. Bei et al. (2012) provided a tighter upper bound on the approximation ratio of the mechanism proposed by Dobzinski et al. (2011). Moreover, Chan and Chen (2016) proposed a budget feasible mechanism for a market in which a dealer aims to maximize its revenue when buying items from sellers and selling them to buyers.

Conclusions

Budget feasible mechanisms are promising for the design and management of a broad set of mobile and wireless systems. They are promising to manage realistic markets that need to be immune against the strategic behavior of the users by achieving incentive compatibility but have a limited budget. This article reviewed the existing budget feasible mechanisms and compared their efficiency in achieving close-to-optimal allocations.

Data falsification in wireless data fusion; Distributed inference with wireless Byzantine data

Definition

Byzantine attack in wireless data fusion means that part of the data from malicious Byzantine attackers may be fake, which makes the results of data fusion deviate from the truth, while Byzantine defense, on the contrast, is the process to decrease negative effects of Byzantine attack on the data fusion via various defense methods.

Historical Background

Byzantine attack stems from the Byzantine generals problem in Lamport et al. (1982) as follows:

A group of Generals of the Byzantine army camped with their troops around an enemy city. Communicating only by messenger, the generals must agree upon a common battle plan. However, one or more of them may be traitors who will try to confuse the others. The problem is to find an algorithm to ensure that the loyal generals will reach agreement.

Based on the illustration above, it is well acknowledged that Byzantine attack exists in various distributed sensor networks (Varshney

1996), e.g., cooperative spectrum sensing in cognitive radio networks (Zhang et al. 2015) and collaborative state estimation in smart grids (Kosut et al. 2011).

In scenarios of wireless data fusion, Byzantine attack is a kind of insider attack in PHY layer, and it refers to the falsification of wireless data (Vempaty et al. 2013). Specifically, in the process of wireless data fusion to make cognition about the wireless environment, lots of devices are equipped and volumes of data are produced. Due to various factors, such as device failure or malicious invasion, part of data sources become Byzantine attackers where data are falsified. As a result, fake data are intermixed with real data, which brings about deviation of data fusion results. In particular, in Marano et al. (2009), Rawat et al. (2011), and Kailkhura et al. (2015), the optimal attack strategies are analyzed, which maximize the detection error probability, and it is pointed out that when Byzantine attackers occupy a certain fraction of all sensors, data fusion scheme with desired performance becomes completely incapable. Hence, robust data fusion is quite challenging in the presence of Byzantine attack. In particular, Chen et al. (2008) is one of the first studies that identifies the problem of Byzantine attack, also known as spectrum sensing data falsification (SSDF) attack, in the context of cooperative spectrum sensing in cognitive radio networks. Further, Ding et al. (2013, 2014) exploit machine learning methods to eliminate fake data, including kernel-based learning and data cleaning methods. During the past decades, Byzantine attack and defense in wireless data fusion have received increasing attentions, especially with the quick development of software-defined radios (SDR). On the one hand, the reconfigurability of SDR enables devices to behave more autonomously, and devices are vulnerable to be invaded and controlled by attackers. On the other hand, the wireless data is closely related to benefits, e.g., spectrum access opportunities, which become the motivation of making data falsification.

Foundations

Wireless data fusion is the process of integrating multiple data sources to achieve more consistent, accurate, and useful information about wireless signals than that provided by any individual data source. Considering the high uncertainty brought by the complicated wireless environment and the special wireless signal propagation characteristic, wireless data fusion is necessary to break the limitation of a single data source through exploiting diversity gains of multiple data sources. Nevertheless, it is built on the basic assumption that all data sources are honest, i.e., the data really reflects the received signal's characteristics. In fact, due to the openness of wireless channels, distributed wireless networks are prone to various security threats, e.g., jamming, spoofing, and wiretap, among which data falsification, i.e., Byzantine attack, breaks the assumption above. In particular, it destroys the inherent relation between the data and the wireless target and deteriorates the reliability of data fusion.

In the past years, Byzantine attack and defense in cooperative spectrum sensing (CSS) have received wide attention, which can be taken as a classic example in wireless data fusion. First, cognitive radio opens a promising paradigm to improve radio spectrum utilization by allowing cognitive or unlicensed secondary users (SUs) to intelligently employ spectrum holes unused by licensed primary users (PUs), where spectrum sensing is one of key enabling techniques to detect spectrum holes. Then, to combat wireless channel impairments, such as multipath fading and shadowing, CSS has been proposed as an effective method to improve the sensing performance by exploiting the spatial diversity among multiple spectrum sensors, but at the same time, Byzantine attack is introduced. Here, the main goals of Byzantine attackers in CSS are twofold: the first is to decrease the detection probability for disturbing the normal operation of PU systems, and the second is to increase the probability of false alarm with the purpose of depriving access opportunities of the honest SUs.

Its attack performance is closely related to several aspects: attack scenario, attack basis, attack opportunity, and attack population (Zhang et al. 2015). Specifically,

- Attack scenario depicts where attackers act in, i.e., the network circumstance. It is classified into centralized and decentralized based on whether there is a dedicated node collecting all sensors' data and making data fusion. It determines the way of sensors cooperating, greatly influencing attack behaviors (Yan et al. 2012), and is chosen as the classification standard of networks.
- Attack basis denotes information based on which malicious users falsify measurements and solves how to launch attacks. Attack basis include local observation, other sensors' sensing results, fusion rules, and so on. An abundant attack basis can assist malicious users to design effective attack strategies.
- Attack opportunity answers about when to attack. At a certain slot, malicious users may decide whether or not to attack with a certain probability. Besides, attackers may take into consideration of this current state, such as sensing results and attack expectation. Attack opportunity reveals the flexibility and variety of attack behaviors.
- Attack population is a basic metric of the Byzantine attack answering about who to attack, and is related to the percentage of malicious sensors in all sensors, dedicating to what degree of severity networks suffers from attackers. Naturally, as the attack population increases, results of data fusion lean more to the Byzantine attacks, and when Byzantine attackers are a certain fraction of all sensors, data fusion scheme becomes completely incapable (Kailkhura et al. 2015).
- Data fusion results. Byzantine data makes the data fusion results biased to certain extend, but when the attack is not very strong, i.e., attack population is lower than 0.5, the bias is not large and can still be used to evaluate the reliability of every data resources (Rawat et al. 2011).
- Trusted data resources' assistance. In certain cases, it is assumed that certain honest sensor is known to the fusion center and its report is approximated as the ground truth of the spectrum state and is used to evaluate other sensors' reports.
- Side information about the wireless environment, including the channel propagation characteristics, e.g., showing correlation (Min et al. 2011), Markovian model for the spectrum state (He et al. 2013), and so on. Side information can be used to extract related parameters of reported data and evaluate the matching degree, based on which the reliability evaluation is done.
- Stale information about real states of the target. The stale information is used to denote information that can reflect the real channel states but is overdue for spectrum sensing in current slot, such as the transmit results, and the whole-slot sensing (Zhang et al. 2016). Although the stale information cannot help spectrum access in current slot, it can assist identification of Byzantine attackers. Its main advantage is that its reliability is rarely affected by the attack behaviors. That means that it can work in severe environments, e.g., Byzantine attackers are in majority.

Further, to exploit all sensors' data instead of abandoning suspicious sensors' data, Ding et al. (2014) proposes a data cleansing-based robust cooperative sensing scheme, where the underutilization of licensed spectrum bands and the sparsity of nonzero abnormal data are jointly exploited to robustly cleanse out the nonzero abnormal data component, not the sensing data itself, from the original corrupted sensing data.

Finally, the Byzantine attack problem is not only a threat in terms of data security but also a

In Byzantine defense, one key problem is how to identify Byzantine attacker, and an effective approach is to build a reference to evaluate the reporters' reliability, which includes but is not limited to the following:

game between attackers and the detection system. On one side, false sensing outputs from malicious alteration ruin the integrity of data and lower the reliability of data fusion. On the other side, like spear and shield, the Byzantine attack and defense are mutually exclusive but indivisible. When launching the attack, the attackers tend to maximize their attack gains, at the same time of considering how to escape from being found by the defense system, while in turn the diversity and flexibility of attack strategies force the defense system to enhance its universality and efficiency. All of these make the issue of Byzantine attack and defense very challenging and quite complicated.

Key Applications

Byzantine attack and defense in wireless data fusion are an important issue of various distributed sensor networks.

Cache Placement and Content Delivery Design in Wireless Caching Networks

Ruijin Sun
Pengcheng Laboratory, Shenzhen, China

Synonyms

Caching strategy; Content transmission strategy

Definition

Cache placement and content delivery design is to allocate the storage resource and the communication resource in wireless networks to achieve better system performance.

Historical Background

With the widespread popularity of smart mobile devices (tablets, pads, phones, etc.) and the development of mobile Internet, the wireless traffic data is increasing explosively. It has been reported in I. Cisco Visual Networking (2017) that the mobile data traffic will grow sevenfold from 2016 to 2021 and will reach 49 exabytes per month by 2021. Meanwhile, the wireless services have been shifted from the traditional voices and messages to the data-craving services, such as

video streaming, online games, augmented reality (AR), virtual reality (VR), and so on. Among them, the video streaming has been the dominant source of the wireless mobile traffic and will make up 78% of the total traffic by the end of 2021 (I. Cisco Visual Networking 2017).

To keep pace with this unprecedented traffic requirement, great efforts have been made to expand the network capacity from both the network architecture evolution and the wireless transmission technologies. For the network architecture evolution, ultra-dense networks are proposed to significantly shrink the cell size for the spectrum reuse. Besides, cloud radio access network (Cloud-RAN) architecture is also put forward to process baseband signals of all base stations (BSs) in a central processor to enhance the system rate. For the wireless transmission technology, massive multiple input and multiple output (Massive MIMO), millimeter wave (mmWave), and visible light communication (VLC) are proposed to improve the network capacity (Wong et al. 2017). All these technologies can boost the peak rate of the network; however, they will lead to high infrastructure cost and heavy backhaul traffic burden.

Wireless edge caching is proposed to deal with this issue from the service transmission characteristics, especially for the video traffic feature. More specifically, 80% of video traffic is caused by 20% popular videos, and the user request probability for the video streaming can be precisely predicted. Therefore, pre-storing popular contents at BSs or mobile devices during off-peak

hours can avoid the redundant transmission in core networks and hence significantly relieve the backhaul traffic burden. As demonstrated in Patel et al. (2014), pre-caching popular contents at BSs can reduce the backhaul traffic to 35%. Moreover, with such local caching, contents are brought much closer to users and thus the content access delay can be considerably reduced. Based on the location of the content caching, wireless caching networks can be classified into two categories: caching at BSs and caching at mobile users. Compared with the BS caching, caching at mobile users with the aid of device-to-device (D2D) communications can further offload the BS traffic to D2D users.

Generally, wireless caching consists of two stages: the caching stage and the delivery stage. In the caching stage, popular contents are stored by BSs or mobile users according to the cache placement algorithm. Then, in the delivery stage, the cached contents can be directly transmitted by BSs or mobile users, which can significantly relieve the backhaul pressure and reduce the end-to-end content delivery delay. As a result, there are two basic issues in wireless caching networks. The first issue is how to reasonably design cache placement algorithm in the caching stage. Different from wired networks, the caching strategy

in wireless networks is more complicated due to the broadcast nature of the wireless channel and the user mobility. The second issue is how to rationally design the content transmission strategy with the given caching status in the delivery stage. Different from traditional wireless networks, the transmission strategy in wireless caching networks should not only consider the channel conditions but also the cache status of BSs and the user requests.

Foundations

The wireless caching network architecture is shown in Fig. 1, which consists of core networks, macro BS (MBS), small BSs (SBSs), and mobile users. The MBS is connected to core networks via the backhaul link, and each SBS is also connected to MBS via the backhaul link. The core networks can access to all contents in the content library. Both BSs (MBS and SBSs) and mobile users are equipped with storage spaces to cache popular contents for the backhaul capacity consumption minimization and the end-to-end delay reduction. Based on this architecture, when a mobile user requests a content, it first searches the content from its own storage. If the requested

Cache Placement and Content Delivery Design in Wireless Caching Networks, Fig. 1 The wireless caching network architecture

content is not cached by the user itself, the user will be served by nearby users via the D2D communication or the BS. If the desired content cannot even be found at BSs, BSs will first fetch the content from core networks and then transmit the content to the user.

Clearly, the caching performance is highly related to the content popularity, which is usually obtained for a certain region during a period of time. According to Breslau et al. (1999), the popularity of all contents in a particular library follows a Zipf distribution. In addition to the general Zipf distribution, the content popularity can also be predicted by analyzing the huge historical content requests and using the machine learning (ML)-based prediction methods. In this way, the specific traffic features and network characteristics for different scenarios can be fully mined. Generally, the content popularity changes much slower than the traffic variation and channel fading of wireless networks. For instance, a hot film may last for one week, while the wireless channel fading always changes at the millisecond level. Therefore, the content popularity is regarded as a constant for a long time.

With the given content popularity, the cache placement and content delivery strategy are designed to optimize the system performance. A commonly used caching performance metric is the cache hit ratio, which is defined as a ratio of the number of user requests being satisfied by local cached contents to the total number of user requests. Except for the cache-based metric, the metric of wireless networks should also be considered. As the pre-caching can effectively relieve the backhaul pressure and considerably reduce the end-to-end delay, the backhaul capacity consumption and the content delivery delay are important metrics to evaluate the caching performance. Besides, traditional system metrics, such as the network capacity, the energy efficiency, the transmission power, the quality of user experience (QoE), and so on, can also be adopted. In the following, we will detail the cache placement and the content delivery design to optimize these caching performance metrics.

Cache Placement Design

Different from wired networks, the caching strategy in wireless networks is more complicated due to the broadcast nature of the wireless channel and the user mobility. Intuitively, it seems that the most popular caching strategy, which stores the most popular contents until the cache capacity is full, can achieve the best system performance, such as the cache hit ratio maximization, the backhaul traffic minimization, the end-to-end delay reduction, and so on. This is true for the single-BS network (Gong et al. 2017). However, for a multi-BS network where users are cooperatively served by all BSs, caching strategies of these BSs will be mutually influenced and should be redesigned considering the user association. With the fixed network topology, the content caching strategies of multiple cache-enabled helpers are jointly optimized to minimize the average content delivery time (Shanmugam et al. 2013). Then, from the perspective of spatial stochastic networks, the caching strategies of multiple BSs are also studied to reduce the average network latency (Zhang et al. 2018).

Furthermore, the user mobility feature also plays a key role in the caching strategy design, especially for high-mobility scenario, e.g., highway communication networks. By modeling the user movements that moving users associate with different BSs as a Markov chain, the caching strategies of multiple BSs are designed to minimize the backhaul traffic load (Poularakis and Tassiulas 2017). Then, for D2D caching networks, an inter-contact model, where each user pair has two states based on the communication region, i.e., the contact state and the inter-contact state, is adopted to characterize the user mobility (Passarella and Conti 2013). Based on this model, mobility-aware caching strategies at mobile users are optimized to maximize the D2D data offload ratio (Wang et al. 2017) and minimize the average transmission cost (Deng et al. 2018), respectively.

Content Delivery Design

With the given caching status, wireless network resources need to be rationally assigned for the content delivery. Different from traditional wire-

less networks, the transmission strategy in wireless caching networks should not only consider the channel conditions but also the cache status of BSs and the user requests. For instance, a user may prefer to associate with a BS caching the requested content to minimize the backhaul traffic load. In Park et al. (2016), for a cloud-RAN scenario where multiple users are cooperatively served by multiple BSs, beamforming vectors of multiple BSs are jointly optimized to improve the system rate. Since different users have a high chance to request the same content, especially when the content popularity distribution is concentrated, the multicast transmission is adopted to minimize the weighted sum of the backhaul traffic load and the transmission power (Tao et al. 2016) and to maximize the weighted sum of users' QoE (Sun et al. 2018). Clearly, the cache placement in the caching stage has a significant impact on the content delivery design. With a reasonable caching strategy, the transmission strategy can be improved, and the system performance can be enhanced.

Key Applications

As pre-caching can effectively relieve the backhaul traffic load and considerably reduce the end-to-end content delivery delay, there is a great interest motivated by profit to deploy wireless caching networks in practice. The network operator can provide cache servers for BSs, and the content provider can lease the storage space of these cache servers to cache popular contents according to caching strategies. Then, a majority of user requests can be directly served by BSs without the backhaul capacity consumption. Note that the deployment of wireless caching networks has no significant infrastructure change and is very cost-effective.

Definition

Network capacity is defined as the total throughput (bps) of all flows in the network;

Network transport capacity is defined as the sum of the products of each flow's throughput and its transceiver distance in the network ($\text{bit} \cdot \text{m/s}$).

Historic Background

The capacity of point-to-point wireless communication over an additive white Gaussian channel was laid out by Claude Shannon in his 1948 seminal paper (Shannon 1948). With the state-of-the-art channel coding, e.g., turbo code, energy and bandwidth efficiency of practical point-to-point communications is pushing closer to the Shannon limit. Due to the broadcast property of the wireless channel, wireless capacity in a multipoint-to-multipoint *networked* environment is interference limited. How to efficiently deploy the spatial utilization of wireless channel to improve the capacity of wireless networks has been a key challenging issue for several decades. In addition to the time and frequency domains, there is the spatial domain that offers diversity/multiplexing gain. Also, the wireless network capacity depends on network topology. Although asymptotic bounds of wireless network capacity have been heavily pursued, how to fully explore the spatial multiplexing gain of wireless networks and determine the capacity of the networks with random topology are still open issues.

To explore the spatial capacity of wireless networks, multiple flows should be scheduled for concurrent transmissions if the transmitters are sufficiently far away from the non-intended receivers. Given a three-dimensional space and a number of active users in the network, what are the expected number of concurrent transmissions, the network capacity, and the transport capacity of networks? Here, the network capacity is defined as the total throughput (bps) of all flows in the network, and the network transport capacity is defined as the sum of the products of each flow's throughput and its transceiver distance in the network ($\text{bit} \cdot \text{m/s}$). In general, the network capacity is the main performance index for single-hop wireless access networks, while the network transport capacity is for multi-hop wireless networks. The analyti-

cal results obtained reveal what the main factors that affect network (transport) capacity are, which will provide important guidelines for wireless network planning, protocol, and architecture design and optimization.

Capacity bounds of wireless networks have been extensively studied in the literature. In the pioneer work of Gupta and Kumar (2000), the asymptotic bounds of network transport capacity have been derived, given the node density in an arbitrary or random wireless network. They extended their work to three-dimensional space in Gupta and Kumar (2001), considering all nodes are located in a sphere. Since then, a large number of follow-up papers have appeared. The impact of user mobility on network capacity has been studied in Grossglauser and Tse (2001) and Jafar (2005). It was found that node mobility can be exploited to increase the network capacity (Grossglauser and Tse 2001), but excessive mobility contrarily limits the capacity (Jafar 2005). The capacity of different networks with different traffic patterns, e.g., relay traffic, convergent traffic, and broadcast traffic, have been investigated in Gastpar and Vetterli (2002), Gamal (2003), and Alireza et al. (2006). These works studied the capacity region, or the upper/lower bounds on network capacity based on the protocol model and the physical model in Gupta and Kumar (2000), assuming that the transmission rate is a binary function with no rate adaptation in the physical layer. In addition, the asymptotic capacity bounds derived in these works may be too loose to be useful in realistic networks where the network topology is random and may change from time to time due to user mobility.

On the other hand, existing theoretical studies indicate that concurrent transmissions should be allowed to improve the resource utilization, as long as all interferers are outside a well-defined exclusive region (ER) around the destinations (Radunovic and Le Boudec 2004; Cai et al. 2009). It is shown in Cai et al. (2010) and Liu et al. (2008) that ER-based resource management can significantly improve the network throughput by exploiting the spatial dimension of the wireless channel. How to control the interference level

Capacity Analysis of Interference-Limited Wireless Networks in Three-Dimensional Space, Fig. 1
Exclusive region for concurrent transmissions

and optimize the exclusive region size to maximize the network capacity and transport capacity of a random network in three-dimensional space are still an open issue.

Key Applications

According to the Shannon limit of an additive white Gaussian noise (AWGN) channel, the upper bound of the achievable data rate of node j is

$$R_j = W$$

$$\log_2 \left(1 + \frac{G_{ij} P_i}{(N_0 W + \sum_{k \in \tau, k \neq i} C_0 G_{kj} P_k)} \right) \text{ bps},$$

where P_i and P_k are the transmission power levels of the sender i and an interferer k , respectively, G_{ij} is the channel gain between nodes i and j , τ is the set of flows that transmit concurrently, C_0 is the cross-correlation coefficient among concurrent transmissions, N_0 is the one-sided power spectral density of additive white Gaussian noise, and W is the signal bandwidth.

In a three-dimensional space, an exclusive region can be a sphere centered at the receiver with radius r , as shown in Fig. 1. In the figure, flows f_1 , f_2 , f_4 , and f_5 can concurrently transmit since all senders are outside the exclusive regions of other receivers; flow f_3 interferes with f_2 or f_4 , and thus they cannot be transmitted concurrently. Different from the guard zone specified in

the protocol model in Gupta and Kumar (2000), the general exclusive region employed in our system model is independent of the transceiver distance but is related to the interference and noise levels.

Without loss of generality, the flows being checked by the scheduling algorithm are labeled by flow 1, 2, ..., N . Given the exclusive region radius r , let $p(k, n)$ denote the probability that k flows satisfy the concurrent transmission condition, after checking the first n ($\leq N$) flows one by one. The first flow f_1 is always scheduled for transmission and added to the set γ and $p(1, 1) = 1$. The second flow f_2 will be added to the set γ if it does not conflict with f_1 . Let the random variable Z be the distance between two devices randomly located in an $l \times l \times h$ three-dimensional (3D) space. Denote Q the probability of another sender outside the exclusive region of a receiver, *i.e.*, the distance between the sender (of flow j) and the receiver (of flow i) is larger than r , $Q = \Pr(d_{j,i} \geq r) = \int_r^{\sqrt{2l^2+h^2}} f_Z(z)dz$, where $f_Z(z)$ is the probability density functions (pdf) of Z (Cai et al. 2009).

Given that the transmitters and receivers are randomly and independently deployed, for flows that can transmit concurrently, the locations of

their receivers are independent to each other. Consequently, given that the transmitter of a flow is outside the ER of the receiver of another flow with probability Q , the probability that two transmitters are outside the ERs of two receivers is Q^2 . Thus, the probability that two flows do not conflict with each other is Q^2 , as each sender should be outside the exclusive region of the other flows' receiver. Accordingly, the probability that two flows conflict with each other is $1 - Q^2$. Therefore, $p(2, 2) = Q^2$ and $p(1, 2) = 1 - Q^2$.

By checking the first n flows, there are k flows in the set γ if (a) there are $k - 1$ flows in γ for the first $n - 1$ flows and the n -th flow does not conflict with the $k - 1$ flows in γ or (b) there are k flows in γ after checking the first $n - 1$ flows, and the n -th flow conflicts with at least one of the k flows.

$$p(k, n) = p(k - 1, n - 1)Q^{2(k-1)} + p(k, n - 1)(1 - Q^{2k}) \quad \text{for } k < n. \quad (1)$$

If only the first flow can be added to γ , implying that the following $n - 1$ flows do not satisfy the concurrent transmission condition, $p(1, n) = (1 - Q^2)^{n-1}$. Another extreme case is that all n flows can transmit concurrently, which means

Capacity Analysis of Interference-Limited Wireless Networks in Three-Dimensional Space, Fig. 2 Expected number of concurrent transmissions vs ER radius

Capacity Analysis of Interference-Limited Wireless Networks in Three-Dimensional Space, Fig. 3 Network capacity vs ER radius ($\alpha = 4$)

Capacity Analysis of Interference-Limited Wireless Networks in Three-Dimensional Space, Fig. 4 Transport capacity vs ER radius ($\alpha = 4$)

that none of the flows conflicts with the remaining $n - 1$ flows $p(n, n) = Q^{(n-1)n}$. Given $p(1, 1)$, $p(1, 2)$, and $p(2, 2)$, $p(k, N)$ can be iteratively obtained as a function of r for $1 \leq k \leq N$. The expected number of concurrent transmissions is thus given by

$$E[N] = \sum_{k=1}^N k p(k, N). \quad (2)$$

Given the transmission distance z' , transmission power P , and the channel gain s between the transmitter and the receiver, the received signal power, P_R , is given by $P_R = K G_T G_R z'^{-\alpha} s P$, where K is a constant G_T and G_R are the antenna gains of the transmitter and receiver, respectively. Accordingly, the achievable data rate of the flow is calculated as $R = \eta W \log_2(1 + \frac{K G_T G_R z'^{-\alpha} s P}{N_0 W + I})$, where η is a constant coefficient related to the efficiency of the transceiver design.

Let the random variable Z' denote the effective transmission distance, which can be represented as a truncated random variable over $[d_{\min}, \sqrt{2l^2 + h^2}]$.

Denote the interference distance and the gain of the channel between the i th interferer to a receiver as random variables V_i over $[r, \sqrt{2l^2 + h^2}]$ and S_i , respectively. The pdf of V_i is given by $f_{V_i}(v) = \frac{f_Z(v)}{\int_r^{\sqrt{2l^2 + h^2}} f_Z(z) dz}$. Given the interference distance v and the channel fading factor s_i , the interference from a single interferer is $I_1 = KC_0G_TG_Rv^{-\alpha}s_iP$.

Given that there are k concurrently transmitting flows, each flow has $k - 1$ interferers. Since the received signal strength and the interference strength are independent R.V.s, the received $SINR$ of a single flow can be obtained as

$$SINR|k \approx KG_TG_RPs_z'^{-\alpha} / [N_0W + (k - 1)I_1]. \quad (3)$$

Accordingly, the average achievable transmission rate and the bit-meter product of a single flow under $k - 1$ interferers are given by

$$E[T_S|k] \approx \iiint \eta W \log_2(1 + \frac{KG_TG_Rz'^{-\alpha}sP}{N_0W + (k - 1)KC_0G_TG_RPv_i^{-\alpha}s_i}) \cdot f_{V_i}(v_i) f_{S_i}(s_i) f_S(s) f_{Z'}(z') dv_i ds_i ds dz', \quad (4)$$

$$E[Tr_S|k] \approx \iiint z' \eta W \log_2(1 + \frac{KG_TG_Rz'^{-\alpha}sP}{N_0W + (k - 1)KC_0G_TG_RPv_i^{-\alpha}s_i}) \cdot f_{V_i}(v_i) f_{S_i}(s_i) f_S(s) f_{Z'}(z') dv_i ds_i ds dz'. \quad (5)$$

Removing the condition of $k - 1$ interferers, $E[T_S]$ and $E[Tr_S]$ can be obtained as $E[T_S] = \sum_{k=1}^N E[T_S|k]p(k, N)$, $E[Tr_S] = \sum_{k=1}^N E[Tr_S|k]p(k, N)$.

The capacity and transport capacity of the network are the sum of the throughput and bit-meter products of all flows concurrently transmitting, which are obtained as $E[T] = \sum_{k=1}^N kE[T_S|k]p(k, N)$, and $E[Tr] = \sum_{k=1}^N kE[Tr_S|k]p(k, N)$.

The expected number of concurrent transmissions, $E[N]$, under various exclusive region sizes is shown in Fig. 2. It can be seen that the expected number of concurrent transmissions decreases when the exclusive region radius r increases.

The network capacity and transport capacity under various ER are shown in Figs. 3 and 4. The experiment parameters are listed in Table 1. It can be seen that the network capacity is bounded by high interference level when r is small; and the capacity becomes constant and equals the average

throughput of a single flow with a TDMA scheme when r is large enough to forbid any concurrent transmissions. Thus, the network capacity is a concave curve as a function of r . Similarly, the transport capacity of the network is also a concave curve under different exclusive region radii, and the maximum transport capacity is achieved when $r = 5$ m.

Capacity Analysis of Interference-Limited Wireless Networks in Three-Dimensional Space, Table 1
Simulation parameters

Signal bandwidth (W)	500 MHz
Transmission power (P)	0.037 mW
Noise power density (N_0)	-117 dBm/MHz
Path loss exponent (α)	4
Reference distance ($d_{\min}$)	1 m
Path loss at $d_{\min}$ (PL_0)	43.9 dB
Cross correlation (C_0)	0.1-1
Nakagami factor (m)	1~6
Transceiver Efficiency (η)	0.189

Definitions

Capacity analysis of wireless networks unveils asymptotic performance limits of the networks and can provide guidance to network planning, protocol design, system improvement and upgrade, etc. This chapter introduces the research works on the capacity of wireless ad hoc networks.

Introduction

Network capacity investigation has been intensive in the past couple of decades. A big chunk of work exploring the capacity of wireless networks has appeared in the literature. There are two obvious reasons for the intense attention on this topic. First, network capacity unveils the asymptotic property of network performance. In face of the emerging large-scale networks of connected objects, such as the Internet of Things (IoT), smart city, smart health, and cyber-physical systems, asymptotic capacity is not a cliché but a very critical issue. Second, network capacity predicts network performance limits as a function of the number of nodes in the network, regardless of detailed protocol design. In contrast, as an alternative way to evaluate network perfor-

mance, simulation or numerical results can only be obtained for a certain number of nodes and are hence deterministic. Besides, these results can only be made available after we design all the network protocols considering every detail and may also require a lot of computing resources and time for large-scale networks. Therefore, capacity investigation can provide guidance to network planning, protocol design, system improvement and upgrade, etc., and is interesting, important, and yet very challenging in wireless networks.

Capacity of Static Ad Hoc Networks

In wireless networks, users communicate with each other over a common wireless channel. Due to the wireless broadcast nature, the capacity of wireless networks is constrained by the bandwidth and the node densities. Gupta and Kumar (2000) show that when using omnidirectional antennas, a static random network with n nodes can provide a per-node throughput at $\Theta(W/n \log n)$ bits per second, where W is the channel capacity and $\Theta(x)$ indicates a function on the same order of x . They also show that even under optimal circumstances, the transport capacity is only $\Theta(W/\sqrt{n})$ bit-meters per second for each node. In other words, wireless networks cannot scale when using omnidirectional antennas. Inspired by this seminal paper, many researchers have investigated the capacity issue for wireless networks under various constraints. In the following, we discuss such research works for static homogeneous ad hoc networks and static heterogeneous ad hoc networks, respectively.

Static Homogeneous Ad Hoc Networks

In static homogeneous ad hoc networks, nodes have the same capabilities such as transmission power, communication bandwidth, antennas, traffic demands, and distributions. Li et al. (2001) examine the capacity of wireless ad hoc networks by using simulations based on IEEE 802.11 pro-

ocols. Agarwal and Kumar (2004b) revisit the capacity problem and derive improved capacity bounds for wireless networks. All these works still show that wireless networks using omnidirectional antennas cannot scale. Later, Ozgur et al. (2006, 2007) study the throughput capacity of wireless ad hoc networks and reveal that by intelligent node cooperation and distributed MIMO communication, wireless networks can scale linearly with the number of nodes.

Directional antennas have emerged as a promising technology due to higher spatial reuse ratio, improved communication distance, and reduced interference. Li et al. (2007, 2009a) study the connectivity problem in wireless networks using directional antennas and demonstrate that directional antennas can improve network connectivity. Using the max-flow/min-cut theorem in flow networks, Peraki and Servetto (2003) show that homogeneous random networks with directional antennas can achieve an increase of $\Theta(\log^2 n)$ in maximum stable throughput compared to random networks with omnidirectional antennas (OTOR networks). As the authors point out in the paper, the problem considered there has certain restrictions to the general one considered in Gupta and Kumar (2000). Yi et al. (2003, 2007) also study the capacity improvement of ad hoc networks using directional antennas. Denote by α and β the beamwidth of a transmitter and of a receiver, respectively. For arbitrary networks, by using a simple directional antenna model without the side lobe gain, they show that the throughput capacity gain is $\sqrt{2\pi/\alpha}$ when using directional transmission and omni reception (DTOR), $\sqrt{2\pi/\beta}$ when using omni transmission and directional reception (OTDR), and $2\pi/\sqrt{\alpha\beta}$ when using both directional transmission and directional reception (DTDR), respectively. For random networks, they show that, by ignoring the side lobe gain, the capacity gain can be $2\pi/\alpha$, $2\pi/\beta$, and $4\pi^2/\alpha\beta$, for DTOR, OTDR, and DTDR networks, respectively. Later on, Li et al. (2011) further investigate the capacity

of ad hoc networks using directional antennas under a practical model. Specifically, they prove that the throughput capacity gain of random directional networks using multihop relay schemes compared to random OTOR networks is at most $O(\log n)$ when the side lobe gain of directional antennas is very small, i.e., when $G_s/G_m = o(1)$, G_m and G_s being the main lobe gain and the side lobe gain, respectively. On the other hand, if random directional networks employ one-hop relay schemes, the per-node throughput capacity can be $\Theta(1)$ when the side lobe gain of directional antennas is very small and the number of beams is very large. They also show that the transmission power of each node can be upper bounded by a constant. In addition, the authors present a lower bound on the transport capacity in arbitrary directional networks and find that without side lobe directional antenna gain, the per-node transport capacity scales as $\Omega(N/\sqrt{n})$, $\Omega(\sqrt{N/n})$, and $\Omega(\sqrt{N/n})$, in arbitrary DTDR, OTDR, and DTOR networks, where N is the number of beams.

Static Heterogeneous Ad Hoc Networks

In static heterogeneous ad hoc networks, nodes have different capabilities and/or follow nonhomogeneous distributions. Kozat and Tassiulas (2003), Liu et al. (2003), Agarwal and Kumar (2004a), Zemlianov and Veciana (2005), Pei et al. (2007), Li et al. (2009b), and Zhang et al. (2010) explore the capacity of ad hoc networks with infrastructure support, where there are n uniformly or regularly distributed nodes and m base stations. Their results generally show that the per-node throughput capacity can scale as $\Theta(1)$ if the number of base stations $m = \Theta(n)$. In other words, such a “hybrid wireless network” can only achieve non-diminishing per-node throughput at the cost of very high infrastructure investment. Later on, Li and Fang (2009) investigate the throughput capacity of hybrid wireless networks with various network topologies and traffic patterns. Particularly, they consider n randomly distributed nodes, out of which there are n source

nodes and n^d ($0 < d < 1$) randomly chosen destination nodes, together with n^b ($0 < b < 1$) base stations in a network area of $[0, n^w] \times [0, n^{1-w}]$ ($0 < w \leq 1/2$). They find that only under certain conditions, i.e., when $d > b$ and $d > w$, the maximum achievable throughput is determined by both the number of base stations and the shape of the network area. In all the other cases, the maximum achievable throughput is only constrained by the number of destination nodes. In addition, Li and Fang (2012) consider a heterogeneous wireless network where there are normal nodes and more powerful helping nodes. They show that network capacity is determined by the shape of the network area, the number of destination nodes, the number of helping nodes, and the bandwidth of helping nodes. They also observe that heterogeneous wireless networks can provide throughput higher in the order sense than traditional homogeneous wireless networks only under certain conditions.

All the above works commonly assume that the nodes are uniformly or regularly distributed, while a few works have studied the network capacity when nodes follow nonhomogeneous distributions. Particularly, Alfano et al. (2009) consider that nodes are placed according to a shot-noise Cox process (SNCP), which is essentially a cluster-based power-law distribution model. Li et al. (2012b) assume that nodes are distributed according to a general nonhomogeneous Poisson process (NPP) in a three-dimensional space. Besides, Li et al. (2014) study the multicast capacity for networks with heterogeneous clusters and explore the effect of heterogeneous cluster traffic on the achievable capacity.

Capacity of Mobile Ad Hoc Networks

Realizing that the mobility is an essence of ad hoc networks, Grossglauser and Tse (2002) investigate the capacity of mobile ad hoc networks for the first time and show that a per-node throughput of $\Theta(1)$ can be achieved with a two-hop relaying scheme. However, they have

not addressed the delay-related issues. After that, a big chunk of work explores the capacity and delay in ad hoc networks, considering many different mobility models, such as Brownian mobility model (Lin et al. 2006), random walk model (Gamal et al. 2004, 2006a,b), i.i.d. model (Lin and Shroff 2004; Neely and Modiano 2005; Toupis and Goldsmith 2004), and hybrid model (Sharma et al. 2007). They all show that a constant per-node throughput can be achieved with end-to-end delay bounded by $\Theta(n)$ with possible logarithmic factors. In general, these results demonstrate that we can only either have low throughput and low delay in static networks or have high throughput and high delay in mobile networks. Note that such works assume global mobility, i.e., nodes can move around the whole network. However, this might not always be the case because in many situations nodes only move within a limited region. Li et al. (2012a) employ a practical restricted random mobility model and present smooth trade-offs between throughput and delay by controlling nodes' mobility. Jia et al. (2017) explore optimal capacity-delay trade-off with correlated mobility models.

Moreover, the aforementioned works study the unicast scenario in which each source node only transmits to one destination node. A few works such as Hu et al. (2009) and Wang et al. (2011) discuss the multicast case. Ying et al. (2008) also propose joint coding-scheduling algorithms to achieve the optimal throughput and delay trade-off.

Conclusions

A substantial body of the literature exists addressing the capacity of wireless networks. As wireless technologies advance, there is no doubt that we will have more and more wireless devices surrounding us, making the scale of wireless networks larger and larger. The research on the capacity of wireless networks will become even more important and challenging because of the dynamics and uncertainty of wireless nodes' positions, capabilities, etc., and the security and privacy issues in the networks.

Synonyms

Cell-less massive MIMO

Definition

Cell-free massive multiple-input multiple-output (MIMO) is a system comprising a very large number of access points (hundreds or thousands of access points) and a relatively smaller number of active users (tens or hundreds of users) distributed over a large area. The access points use directly measured channel characteristics to jointly serve all users in the same time-frequency band. There are no cells or cell boundaries.

Historical Background

Conventional mobile networks are based on cellular structure where a coverage area is divided into cells, and each cell is served by one access point/base station. These networks are called “cellular wireless networks.” We have seen many revolutions related to the cellular wireless network since its first trial was introduced in the 1970s (Young 1979). Intercell interference is one of the inherent limitations of cellular networks. In particular, users at the cell boundaries perform badly due to the strong intercell interference which limits the performance of the whole networks. To reduce this bottleneck, network MIMO (aka coordinated multipoint with joint transmission, distributed MIMO, and distributed antenna systems) was introduced in the 2000s (Shamai and Zaidel 2001). In network MIMO, the base stations cooperate to serve the users. More precisely, the coverage area is divided into

several disjoint clusters; each is jointly served by several base stations. Basically, network MIMO is equivalent to the cellular network with larger cell size, and each cell is served by multiple base stations. There are still concepts of cells and cell boundaries, and hence, the intercell interference persists. In addition, normally, network MIMO requires complicated signal co-processing with high backhaul overhead and deployment costs.

Cell-free massive MIMO was introduced in 2015 as a practical and scalable version of network MIMO (Ngo et al. 2015). The journal version of (Ngo et al. 2015) was published in 2017 (Ngo et al. 2017). The authors of (Ngo et al. 2015, 2017) showed that cell-free massive MIMO can offer uniformly very good service for all users with very simple maximum-ratio processing. Furthermore, it outperforms the conventional small-cell systems. Recently, cell-free massive MIMO has attracted substantial research interest. The performance of cell-free massive MIMO with zero-forcing processing was studied in (Nayebi et al. 2017) under max-min fairness power controls and in (Nguyen et al. 2017) under energy efficiency optimization. The aspects of channel favorable and channel hardening were investigated in (Chen and Björnson 2017). In (Interdonato et al. 2016), the authors proposed to use beamformed downlink training to estimate the effective channel gains at each user. With this scheme, the system performance improves substantially. The studies of cell-free massive MIMO under practical constraints were exploited in (Huang and Burr 2017), (Bashar et al. 2018), and (Zhang et al. 2017). Papers (Huang and Burr 2017; Bashar et al. 2018) focus on the limited backhaul connections, while paper (Zhang et al. 2017) investigates the effect of hardware impairments on the performance of cell-free massive MIMO. It is shown that under practical constraints, cell-free massive still works well, especially when the number of access points grows large. Another approach to implement cell-free massive MIMO, called user-centric approach, was exploited in (Buzzi and D'Andrea 2017) and Ngo et al. (2018). Both papers show that if each user is served by several selected access points, the

backhaul requirement reduces significantly, while the system performance is still good.

How Cell-Free Massive MIMO Works

A basic cell-free massive MIMO system is illustrated in Fig. 1. It includes M access points and K users. The access points and users can be equipped with a single or several antennas. Central processing unit (CPU) connects to the access points via a backhaul network to control the data streams and network synchronization and allocate powers.

As in conventional massive MIMO, in cell-free massive MIMO, time-division duplex (TDD) operation is preferable. This is due to the fact that the channel estimation overhead in TDD operation is independent of the number of access points. It depends only on the number of users. As a result, by leveraging TDD, cell-free massive MIMO is scalable in the sense that adding more access points will not affect the operation

of the channel estimation and, hence, is always beneficial for increased data rate. The TDD transmission protocol is shown in Fig. 2. During a coherence interval of length τ_c symbols, there are three activities: uplink training (τ_p symbols), uplink data transmission (τ_u symbols), and downlink data transmission (τ_d symbols). The uplink channels are estimated at the access points based on the pilot signals transmitted from the users. By virtue of reciprocity, these uplink channel estimates are treated as the downlink channels. Thus, the uplink channel estimates can be used for data detection in the uplink and for processing the transmit signals in the downlink:

- *Uplink training:* in this phase, all users first send their pilot sequences of length τ_p symbols to the access points. Then from the received pilot signals, each access point estimates all its channels to the users. Typically, the linear minimum mean-square error estimation technique is used. If the coherence interval is large (relative to the

Cell-Free Massive MIMO,
Fig. 1 Cell-free massive MIMO system

Cell-Free Massive MIMO,
Fig. 2 TDD transmission protocol

number of users K), then we can choose $\tau_p \geq K$, and hence, the pilot sequences assigned for the K users can be pairwise orthogonal. Otherwise, non-orthogonal pilot sequences have to be used throughout the network. The channel estimate of a given user is contaminated by pilot signals transmitted from other users. This degrades the system performance, even when the number of access points is very large. This effect is called “pilot contamination effect”.

- *Uplink payload data transmission*: in this phase, all users simultaneously send their signals to the access points. Each access point uses its local channel estimates to process the received signals and sends the processed version to the CPU. The CPU then detects all signals transmitted from all K users. Simple linear processing such as maximum-ratio processing (aka matched filtering) is recommended at each access point. Alternatively, signal processing can be done at the CPUs. With this scheme, the APs need to forward their channel estimates and received data to the CPU for signal detection.
- *Downlink payload data transmission*: in this phase, the access points use their local channel estimates to precode the symbols intended for all K users (these symbols are sent from the CPU) and broadcast the precoded versions to the users. Each user then detects the desired symbol from the received signal. Simple linear processing such as maximum-ratio processing (aka conjugate beamforming) is recommended at each access point.

Why Cell-Free Massive MIMO

Cell-free massive MIMO is the combination between distributed structure and massive MIMO technology. Thus, it reaps all benefits obtained from these systems:

- *Uniformly good service for all users in the network*: in cell-free massive MIMO, the access points are spread out over a large area. In other words, many access points are brought close to the users which yields low path losses and

an increased macro-diversity. As a result, it can offer a very high probability of coverage and uniformly good service for all users.

- *Huge spectral and energy efficiency*: by exploiting the favorable propagation property when the number of access points is large (the channel vectors between the users and all access points are (nearly) pairwise orthogonal), many users can be served simultaneously in the same frequency band with small inter-user interference. Thus, a huge spectral efficiency can be obtained. In addition, with massive number of access points, cell-free massive MIMO can focus the energy to the locations of its desired users. As a result, it can offer very high energy efficiency.
- *Simple signal processing*: owing to the favorable propagation, cell-free massive MIMO can achieve very good performance with simple linear processing such as maximum-ratio or zero-forcing processing. In addition, from the law of large numbers, uncorrelated noise and small-scale fading can be averaged out. Therefore, the system design (e.g., power controls and pilot assignments) depends only on the large-scale fading.

Example

To clarify the benefits of cell-free massive MIMO mentioned above, consider the downlink transmission of a simple cell-free massive MIMO system where M access points serve two users. All access points and users are equipped with a single antenna. It is assumed that the access points have perfect channel state information (the uplink training is perfect) and use maximum-ratio processing to precode the signals.

Denote by g_{mk} the channel between the m th access point and the k th user. The channel g_{mk} models large-scale fading (path loss and shadowing) β_{mk} and small-scale fading h_{mk} as follows:

$$g_{mk} = \sqrt{\beta_{mk}} h_{mk}. \quad (1)$$

We assume that h_{mk} is Gaussian distributed with zero mean and unit variance. Let q_k , where

$\mathbb{E}\{|q_k|^2\} = 1$, be the symbol intended for the k th user. Then, with maximum-ratio processing, transmitted signal from the m th access point is

$$x_m = \sqrt{\frac{\rho}{\beta_{m1} + \beta_{m2}}} (g_{m1}^* q_1 + g_{m2}^* q_2). \quad (2)$$

The factor $\sqrt{\frac{\rho}{\beta_{m1} + \beta_{m2}}}$ guarantees that the normalized transmit power of the access point is ρ , i.e., $\mathbb{E}\{|x_m|^2\} = \rho$. To precode the symbols q_1 and q_2 as in (2), the m th access point only needs to know its local channels g_{m1} and g_{m2} which can be estimated during the training phase. Thus, channel state information does not need to be shared among the access points.

Focus on user 1. The same analysis can be done for user 2. Since all M access points simultaneously broadcast their signals, user 1 receives

$$y_1 = \sum_{m=1}^M g_{m1} x_m + n_1, \quad (3)$$

where n_1 is the additive noise at user 1. We assume that n_1 is Gaussian distributed with zero mean and unit variance. Substituting (2) into (3), we obtain:

$$\begin{aligned} y_1 &= \sum_{m=1}^M g_{m1} \sqrt{\frac{\rho}{\beta_{m1} + \beta_{m2}}} \\ &\quad (g_{m1}^* q_1 + g_{m2}^* q_2) + n_1 \\ &= \underbrace{\sum_{m=1}^M \sqrt{\frac{\rho}{\beta_{m1} + \beta_{m2}}} |g_{m1}|^2 q_1}_{\text{desired signal}} \\ &\quad + \underbrace{\sum_{m=1}^M \sqrt{\frac{\rho}{\beta_{m1} + \beta_{m2}}} g_{m1} g_{m2}^* q_2}_{\text{interference and noise}} + n_1. \end{aligned} \quad (4)$$

By Chebyshev's theorem (which is the general version of the law of large numbers), when the number of access points goes to infinity, we have:

$$\frac{\text{desired signal}}{M}$$

$$- \frac{1}{M} \sum_{m=1}^M \sqrt{\frac{\rho}{\beta_{m1} + \beta_{m2}}} \beta_{m1} q_1 \xrightarrow{P} 0, \quad (6)$$

$$\frac{\text{interference and noise}}{M} \xrightarrow{P} 0, \quad (7)$$

where $\xrightarrow{P}$ denotes convergence in probability.

It can be seen from (6) and (7) that, when the number of access points grows large, the desired signals are added up coherently from all access points, while the interference is averaged out. As a result, the received signal at user 1 normalized by M is

$$\frac{y_1}{M} - \frac{1}{M} \sum_{m=1}^M \sqrt{\frac{\rho}{\beta_{m1} + \beta_{m2}}} \beta_{m1} q_1 \xrightarrow{P} 0. \quad (8)$$

This implies that when M is large, the interference from user 2 and noise are canceled out. The desired signal normalized by M includes only the desired symbol q_1 . Unlimited capacity can be achieved.

Challenges and Open Problems

Despite the huge advantages of cell-free massive MIMO, many challenges still need to be tackled:

- **Backhaul requirements:** cell-free massive MIMO requires huge backhaul connections and signaling, especially when the number of access points is very large. Therefore, suitable transmission approaches should be investigated to make cell-free massive MIMO feasible for practical implementations. One possible approach is the user-centric approach. With user-centric approach, each user is served by some chosen access points around it. In addition, multiple CPUs can be used.
- **Synchronization:** the system needs to be synchronized so that all access points can coherently serve all users. In cell-free massive MIMO, since the numbers of access points and users are very large, and the access points/users are located randomly in a very large area, the network synchronization is

very challenging. New simple methods which can synchronize the cell-free massive MIMO networks with low cost should be investigated.

- **Channel state information acquisition:** acquisition of channel state information is very important in cell-free massive MIMO. This is done via the uplink training under TDD operation. In general, the number of users is large, while the coherence interval is limited. Thus, it does not guarantee that the pilot sequences assigned for all users are pairwise orthogonal. This causes pilot contamination effect and degrades the system performance significantly. Therefore, good pilot assignment methods or/and good channel estimation algorithms to reduce the pilot contamination effect need to be exploited.

Key Applications

Cell-free massive MIMO can be applied in every wireless networks, particularly in mobile networks, device-to-device communications, and machine-type communications such as the Internet of Everything, Internet of Things, and Smart X.

Cellular and mobile communication networks

Definitions

A cellular network is a wireless communication network which provides services to mobile users covered by a region consisting of multiple cells. Frequency reuse is a fundamental concept in cellular networks.

Historical Background

Prior to the invention of cellular technologies, there were few mobile telephone systems in the late 1940s in the USA and in the early 1950s in Europe, such as car-based telephone systems. The push-to-talk technique was used in these systems, and communication was performed over a single channel. With a single channel and a single antenna at each device, the transmission and reception of signals were performed in a half-duplex manner. Due to low capacity, restricted mobility support, and poor service quality, those systems were not efficient. Later on, mobile telephone system (MTS) and improved MTS (IMTS) were introduced in order to support a larger number of mobile stations. IMTS adopted two channels, one for sending and one for receiving, allowing mobile communication to work in a full-duplex mode. However, the concept of *cells* did not apply to these pre-1G mobile communication systems.

The breakthrough for increasing capacity appeared in the 1970s when the technique for *frequency reuse* was developed by dividing a coverage region into multiple cells and reusing

the same frequency at different cells which are sufficiently far away from each other. In 1979, the first 1G cellular network was launched in Japan. In 1981, the first international cellular network, Nordic Mobile Telephone (NMT) systems, came to operation in Nordic countries. In 1983, two other 1G systems, Advanced Mobile Phone System (AMPS) and Total Access Communication System (TACS), were introduced in the US and other European countries including the UK and Italy, respectively.

Through a journey which started about 40 years ago, cellular communications have experienced dramatic changes and upgrades from 1G to 4G. Those transitions include the system change from analog to digital, the core network evolution from circuit-switched to packet-switched technologies, and its further transfer toward all Internet Protocol (IP) networks.

First-Generation Cellular Systems

The 1G mobile systems were designed for providing voice services only and were developed based on analog technologies. For medium access of multiple users, frequency-division multiple access (FDMA) schemes were adopted. For carrying voice traffic, frequency modulation (FM) was employed as the modulation scheme.

Nordic Mobile Telephone Systems

NMT is a mobile telephone network covering first the five Nordic countries, Denmark, Finland, Norway, Sweden, and Iceland, and later quite a few other countries. NMT has two variants based on the operational frequency bands, known as NMT-450 and NMT-900, respectively. NMT-450 was developed in order to establish a compatible telephone system in the Nordic countries (Nordic Mobile Telephone Group 1995). Initially NMT-450 targeted at deploying macro cells at the 450 MHz band to provide larger cell coverage, and later it was modified to operate in the 900 MHz band by considering the size and transmission power constraint of handsets. NMT systems were initially launched in Norway and

Sweden as a national service, and later on it was enhanced with roaming services across countries. NMT-900 bears more channels than the NMT-450 network, able to serve a higher number of subscribers.

Advanced Mobile Phone System

The AMPS systems were deployed in North America. It has 2×20 MHz bandwidth within the 800–900 MHz frequency band (825–845 MHz for uplink and 870–890 MHz for downlink traffic respectively) allocated by the Federal Communications Commission (FCC). With 30 kHz bandwidth for each channel, it provides 832 duplex channels. This system employs seven-cell clusters for frequency reuse and uses mainly 120° sector antennas. Three sectors for a single AMPS cell site were designed to achieve a carrier-to-interference ratio of 18 dB with satisfactory voice quality. In 1991, an improved version of AMPS named as narrowband AMPS (N-AMPS) was developed to further increase AMPS capacity with additional advanced features such as authentication and caller ID.

Total Access Communication Systems

TACS was the first standard that used the 900 MHz band and was deployed in other European countries (Goldsmith 2005). TACS was operated at a higher frequency than AMPS and adopted narrower bandwidth per channel (25 kHz in TACS versus 30 kHz in AMPS). With narrower bandwidth for each channel, the total number of channels is increased for a band with fixed bandwidth. Operated at a higher frequency, the coverage for each cell will be reduced given the same transmission power and channel condition. In other words, this system was designed for having higher capacity rather than coverage by deploying a larger number of cells and allowing lower transmission power for mobile stations. Indeed, TACS was proved to be efficient and economical for highly dense urban areas. A variant of TACS, J-TACS, was also adopted in Japan.

Second-Generation Cellular Systems

The core network of both 1G and 2G cellular networks was built based on circuit-switched technologies, and the service was mainly targeted at voice traffic. However, unlike 1G systems, 2G employed *all-digital* transmission technologies for both control signaling and data traffic. The introduction of digital communication provides a series of important features such as the support of advanced source and channel coding, more efficient spectrum utilization, and a high degree of resistance against interference and channel fading. In addition, the handling of control information is more efficient in digital systems.

2G cellular networks were deployed worldwide. They are represented by four major standards, i.e., Global System for Mobile communications (GSM), Interim Standard (IS)-136 or Digital AMPS (D-AMPS), IS-95 or cdmaOne, and Personal Digital Cellular (PDC). Except cdmaOne, the other three systems are based on time-division multiple access (TDMA) mechanisms for medium access. TDMA allows multiple users to share the same channel in the frequency domain by allocating a specific short period of time, known as time slot, to each user for their channel access. Among these four standards, GSM is the most popular 2G technology. Given the fact that 3G and 4G are already widely deployed in the world as of 2017, GSM still occupies approximately 39% of the global mobile market share.

Global System for Mobile Communications

In 1982, a committee called *Groupe Spécial Mobile* was established in order to design a Pan-European digital cellular standard for mobile communications which would replace the incompatible 1G analog systems. The European Telecommunications Standards Institute (ETSI) initiated the development of the first version of GSM, and the first GSM call was made in 1991. The success of GSM is represented by its over 90% market share in the 2G world, covering globally around 200 countries and territories.

GSM is operated mainly in three frequency bands, i.e., GSM-900, GSM-1800, and GSM-

1900 with 124, 374, and 299 radio channels, respectively. The original GSM network was developed for voice communication supporting a variety of voice codecs. The bandwidth for each GSM channel is 200 kHz, and there are eight time slots in each frame which lasts for 4.615 ms. The raw data transmission rate achieved at each channel is 270.833 kbps, and it is shared by eight users. With the combination of TDMA and FDMA, GSM provides the capability of simultaneous conversations at the same frequency through different time slots. Other salient features of GSM include data encryption, subscriber identity module (SIM) card which gives a unique identity to each mobile station, and global roaming (Eberspächer et al. 2009). Furthermore, GSM is enhanced to provide short message service (SMS), however, still based on circuit-switched technologies.

GPRS and EDGE

To support higher data transmission rates in GSM networks and provide IP services without replacing the network infrastructure, developments were made to upgrade GSM networks into General Packet Radio Service (GPRS) in year 2000. GPRS is also known as 2.5G, and there are two major enhancements for the evolution from GSM to GPRS. At the radio access network, a user is allowed to occupy up to five time slots so that 114 and 20 kbps are achieved for downlink and uplink traffic, respectively. At the core network, two entities, Serving GPRS Support Node (SGSN) and Gateway GPRS Support Node (GGSN), are introduced. With the support of Packet Data Protocol (PDP) and GPRS Tunneling Protocol (GTP), end-to-end IP services can be provided.

In 2003, there was another improvement in GSM systems with the deployment of Enhanced Data rates for GSM Evolution (EDGE) networks. EDGE is regarded as an extension of the GPRS radio access network through advanced modulation schemes. It increased the data rates to 384 kbps for downlink and 60 kbps for uplink, respectively.

Third-Generation Cellular Systems

While GSM was in its early stage, the standardization of the next-generation mobile telecommunication network was also initiated by ETSI aiming to develop a new system called Universal Mobile Telecommunications System (UMTS). High spectrum efficiency, data rates up to 2 Mbps, variable bit rates, QoS requirements based on service types, support of asymmetric uplink and downlink traffic, and coexistence with 2G systems are the main requirements for 3G systems (Holm and Toskala 2007). Meanwhile ITU commenced proposing recommendations for 3G systems known as International Mobile Telecommunications 2000 (IMT-2000) and started to investigate suitable spectrum for 3G. The establishment of the 3rd Generation Partnership Project (3GPP) in 1998 became a milestone for the standardization of cellular networks as a *global* standard from 3G and beyond. In Table 1, we summarize 3GPP releases and their main features. Note that current 4G and upcoming 5G standards are also standardized by 3GPP.

The key mechanism used for medium access in 3G is CDMA which allows multiple mobile stations to transmit at the same time and in the same frequency band. In a CDMA cell, each subscriber is assigned a unique code, and the codes assigned to different stations are orthogonal to each other. As such, the number of simultaneous calls in a CDMA cell is soft limited (based on the interference level), not hard limited as in GSM.

UMTS WCDMA

Wideband CDMA (WCDMA) was the air interface for the UMTS standard originally proposed by ETSI in 1998. To provide peak data rates from 384 kbps to 2.048 Mbps, the WCDMA system operates on wider channels each with 5 MHz bandwidth. However, the core network architecture of UMTS remains the same as the existing GSM/GPRS networks.

WCDMA is a direct-sequence spread spectrum (DSSS) system which initially operates in the 1885–2025 MHz and 2110–2200 MHz frequency bands for uplink and

Cellular Networks: An Evolution from 1G to 4G, Table 1 3GPP release dates and features

3GPP release	Start/release date	Summary of key features
R99	1996/2000	First release of the UMTS standard
R4	1998/2001	This release added features including an all-IP core network. It was originally referred to as Release 2000
R5	2000/2002	IP Multimedia Subsystem and High-Speed Downlink Packet Access (HSDPA)
R6	2000/2004	Integrate the operation of UMTS with wireless LAN networks and added enhancements to IMS (including push-to-talk over cellular), and it added High-Speed Uplink Packet Access (HSUPA)
R7	2003/2007	Detailed improvements to QoS for applications such as VoIP and upgrades for High-Speed Packet Access (HSPA+) Evolution as well as changes for EDGE
R8	2006/2008	Provide details for the LTE System Architecture Evolution, SAE, an all-IP flat network architecture providing the capacity and low latency required for Long-Term Evolution (LTE) and future evolutions
R9	2008/2009	Further enhancements to the SAE as well as allowing for WiMAX and LTE/UMTS interoperability
R10	2009/2011	Up to 3 Gbps downlink and 1.5 Gbps uplink, carrier aggregation (CA), relay nodes to support heterogeneous networks, higher-order MIMO antenna configurations
R11	2010/2012	Enhancements to carrier aggregation, MIMO, relay nodes, coordinated multi-point transmission and reception to enable simultaneous communication with multiple cells, introduction of new frequency bands
R12	2011/2015	Enhanced small cells for LTE, inter-site carrier aggregation, interworking between LTE and Wi-Fi or HSDPA
R13	2012/2016	LTE-U, LTE for machine-type communication (MTC), full-dimension MIMO, LTE Advanced Pro
R14	2015/2017	Energy efficiency, location services, mission-critical data and video, massive IoT
R15	2016/2018	5G Phase 1 (new radio)
R16	2017/2019-2020	5G Phase 2

downlink, respectively. It supports operation modes of both frequency-division duplex (FDD) when symmetric uplink/downlink channels are available and time division duplex (TDD) when only asymmetric spectrum is available. In addition to achieving higher data rate, the support for multi-code operation, larger number of spreading factors, and enhanced transmission diversity are the key factors which lead WCDMA to the most popular 3G technology. Moreover, for the purpose of leveraging the GSM coverage for WCDMA, seamless handovers between GSM and WCDMA are also supported as well as dual-mode handsets.

High-Speed Packet Access (HSPA)

HSPA includes two phases as the beyond UMTS WCDMA enhancements by 3GPP, i.e., HSDPA

in R5 and HSUPA in R6. The main idea of HSDPA is to increase downlink data rate through techniques including adaptive modulation and coding (AMC), hybrid automatic repeat request (HARQ), and fast packet scheduling. Unlike in the previous standards, the medium access control (MAC) layer of HSDPA systems is installed at the base station, i.e., NodeB. Thus, retransmissions can be controlled directly by NodeB, leading to faster retransmission and accordingly shorter delay with packet data operation (Holm and Toskala 2007). HSDPA is capable of supporting up to 14.4 Mbps peak theoretical throughput. Similarly HSUPA is developed to support enhanced packet data throughput for uplink. HSUPA enables additional features such as fast power control and variable spreading factors which are disabled in HSDPA.

However, HSUPA does not support AMC. It is capable of providing up to 5 Mbps peak uplink throughput.

Fourth-Generation Cellular Systems

The data rate provided by 3G networks was not able to meet the growing demand for Internet access via mobile phones. From 2008, ITU's Radiocommunications Sector (ITU-R) initiated the process for developing a new system known as IMT-Advanced. The main requirements for this new system include supporting 100 Mbps and 1 Gbps peak data rate for high- and low-mobility scenarios, respectively, bandwidth scalability up to 100 MHz, mobility support with up to 350 km/h, 10 ms user plane latency and 100 ms control plane latency, worldwide roaming capability, inter-networking with other 2G and 3G systems, and improved spectral efficiency (Korhonen 2014). Radio technologies that could meet these requirements are termed as 4G systems. LTE Advanced (LTE-A) developed by 3GPP is regarded as the de facto 4G mobile communications system from a global perspective. Although LTE does not meet the requirements for 4G as specified by ITU, it is often marketed as a 4G technology.

LTE

LTE is presented here under the 4G umbrella considering the fact that both LTE and, the *true* 4G technology, LTE-A, are based on orthogonal frequency-division multiplexing (OFDM)/OFDM access (OFDMA) mechanisms for medium access. LTE supports both FDD and TDD operations and provides flexible operations in both symmetric and asymmetric spectra. To enhance uplink power efficiency, LTE adopts single-carrier frequency-division multiple access (SC-FDMA). To achieve higher data rate, LTE offers flexible bandwidth allocation up to 20 MHz. Moreover, much shorter frame sizes (10 ms frames and 1 ms sub-frames) are introduced. With a configuration of 20 MHz spectrum and 4×4 MIMO, 326 Mbps on the

downlink and 86 Mbps on the uplink can be achieved in LTE radio networks.

To upgrade LTE core networks, 3GPP R8 introduced Evolved Packet Core (EPC) which was designed to provide higher capacity, all-IP support, and reduced latency. Unlike the hierarchical architecture used in GPRS and UMTS core networks, the main design principle in EPC was to keep the architecture simple and flat.

LTE Advanced

The LTE-A standard ratified by 3GPP R10 is the major standard for 4G. Many of the existing features in R8 are inherently supported in LTE-A. In addition, carrier aggregation up to five component carriers, use of relays, higher-order MIMO, and enhanced inter-cell interference coordination (eICIC) served as new features in LTE-A. Furthermore, in R11, coordinated multipoint (CoMP) transmission and reception and enhanced self-organizing network (SON) are designed as parts of the LTE-A networks.

The same as in LTE, the medium access mechanism in LTE-A adopts OFDMA for downlink and SC-FDMA for uplink. The main advantages of OFDMA include the ability to gain much frequency diversity through randomly distributed subcarriers, multiuser diversity via assigning contiguous sets of subcarriers, and adaptive bandwidth allocation. To increase transmission power efficiency and reduce the cost of power amplifiers for mobile stations, SC-FDMA is employed thanks to its low peak-to-average power ratio. At the physical layer, adaptive coding and modulation (ACM) is adopted in 4G systems. With ACM, the modulation order and the coding rate are fine-tuned based on the channel state information to gain the full use of radio channels.

Another technique for data rate enhancement is channel aggregation which assembles multiple channels together to perform data transmission over wider bandwidth. Furthermore, LTE-A continues to improve capacity and reliability through more advanced MIMO technologies. While single-site MIMO introduces beamforming, spatial multiplexing, and transmit diversity into the system, cooperative MIMO facilitates CoMP transmission and reception. Under CoMP,

a mobile station is able to receive signals from multiple base stations and likewise for the uplink transmission. By adopting a proper coordination scheme, the received signal quality is greatly improved.

Due to the fact that mobile stations cannot support MIMO with many antennas, cell-edge users may not obtain 4G-level quality of service, although a large number of antennas can be installed at the base station. To improve the performance of these users, relaying is adopted as a cooperative communication technique where single-antenna mobile stations transmit their signals to the base station via a relay station that is located much closer to the cell edge (Sesia et al. 2011). Another critical requirement for IMT-Advanced is effective power management. The aforementioned techniques including SC-FDMA, advanced multi-antenna design, and relaying collectively contribute to significant reduction of mobile station power consumption.

Key Applications

On its journey from 1G to 4G, cellular networks experienced FDMA-based analog systems (NMT, AMPS, TACS), TDMA-based digital systems (GSM, GPRS), CDMA-based IP-enabled systems (WCDMA, HSPA), and OFDM-based broadband mobile systems (LTE/LTE-A). The core network of cellular systems has gradually evolved from a circuit-switched telephone network to a packet-switched mobile network with an all-IP capability. Another trend along with this evolution is that nowadays cellular technologies are being developed as a global common standard in lieu of multiple regional standards developed in the early years which were not compatible with each other.

Cellular Unlicensed Spectrum Technology

Jeongho Jeon and Tom Cruz
Intel Corporation, Santa Clara, CA, USA

Synonyms

[License-Assisted Access. \(Not Licensed-...\)](#)

Definition

Cellular unlicensed spectrum technology is a collective term that refers to cellular technologies exploiting the unlicensed band spectrum.

Historical Background

The first and foremost example was designed by the 3rd Generation Partnership Project (3GPP),

which is Long-Term Evolution (LTE) License-Assisted Access (LAA) technology (Kwon et al. 2017). LAA received its name from the system's design, in which it only allows the use of unlicensed carriers when it is operated together with a licensed carrier. LTE LAA has been developed in multiple phases: Rel-13 LAA Study Item (SI) phase, Rel-13 LAA Work Item (WI) phase, Rel-14 enhanced LAA (eLAA) WI phase, and Rel-15 further enhanced LAA (FeLAA) WI phase. FeLAA in Rel-15 is currently ongoing. Similar to 3GPP, MulteFire has been specifying the stand-alone unlicensed system, a system designed to operate on unlicensed carriers without the need of a licensed carrier ([Online]. Available: <http://multefire.org>). MulteFire is an additional feature specification to the 3GPP LTE LAA design to enable stand-alone unlicensed operation. Note that MulteFire is not a part of 3GPP. On the other hand, 3GPP is currently in the phase of developing New Radio (NR), the next generation radio access technology for International Mobile Telecommunications (IMT) 2020. NR is being developed assuming the use of licensed carrier in the first phase. It is planned to start the feasibility of operating NR using unlicensed spectrum in late 2017 (RP-170828 2017).

Standardization History

3GPP Rel-13 LAA SI

The objective of the Rel-13 LAA SI was to study the feasibility of LTE operation in unlicensed spectrum with the focus on fair coexistence with incumbent systems, e.g., Wi-Fi, and meeting the regulatory requirements (Technical Report 36.889 2015). An extensive simulation campaign had been conducted with the participation of both cellular and Wi-Fi industries. The evaluation results showed that the LAA technology can indeed fairly coexist with Wi-Fi networks for various traffic types including, but not limited to, File Transfer Protocol (FTP) and Voice over IP (VoIP) traffic, if a listen-before-talk (LBT) mechanism, similar to that of Wi-Fi, is augmented to LAA. Accordingly, the conclusion

of the SI was that "it is feasible for LAA to fairly coexist with Wi-Fi and other LAA networks if an appropriate channel access scheme is adopted." The LAA SI phase took place during the first half of 3GPP Rel-13 from late 2014 to mid-2015.

3GPP Rel-13 LAA WI

As the LAA SI transitioned into a WI, the objective became the specification of LTE Downlink (DL) operation using unlicensed secondary cell(s) (SCell) with a licensed primary cell (PCell) (RP-151045 2015). The LAA technology is a global single solution, which was designed to meet different regional regulatory requirements. Just as in Rel-13 LAA SI, ensuring the fair coexistence with existing Wi-Fi networks remained as the highest priority. Consequently, the specification of the channel access mechanism, including the LBT procedure, was the main focus. The LAA WI was conducted during the second half of 3GPP Rel-13, beginning in mid-2015 and completed in late 2015.

3GPP Rel-14 eLAA WI

Following the Rel-13 LAA WI, a new WI was created with the objective to enable the LTE Uplink (UL) operation on the unlicensed carrier in addition to the DL operation defined in Rel-13. The Rel-14 LAA WI was titled enhanced LAA (eLAA) (RP-152272 2015). The channel access mechanism for the UL fundamentally resembles that of the DL. The LBT mechanism, which was first incorporated in Rel-13 for the DL, was now tailored to operate for UL. In addition, the channel occupancy sharing mechanism between the DL and UL was defined. The UL control channel and the random access channel for the initial access were not defined for an unlicensed carrier as they stay associated with a licensed UL carrier. The eLAA WI was conducted during 3GPP Rel-14 from early 2016 to late 2016.

3GPP Rel-15 FeLAA WI

3GPP is currently conducting the specification for further enhanced LAA (FeLAA) WI within the Rel-15 time frame, and it is scheduled to finish by early 2018 (RP-170848 2017). One objective of the FeLAA WI is to specify the sup-

port for multiple starting and ending positions in a subframe for UL and DL on an unlicensed carrier. This new design would further enhance the coexistence with neighboring systems by improving the efficiency of unlicensed resource utilization by defining finer granular starting and ending positions of a transmission by LAA. Another objective is to study and specify the autonomous uplink access, which does not rely on a UL scheduling grant for transmission. This objective was motivated to enhance the LAA UL performance from that of Rel-14.

Key Technical Components

Listen-Before-Talk

The adoption of LBT in LAA system was crucial in achieving fair coexistence with neighboring systems sharing the unlicensed spectrum in addition to the regulatory requirements. The LBT mechanism by LAA fundamentally resembles the WLAN's carrier sense multiple access with collision avoidance (CSMA/CA) (IEEE Std 802.11TM-2012 [2012](#)). A node that intends to transmit first performs channel sensing before transmission. The purpose of the additional random backoff mechanism is to avoid collisions when more than one node senses the idle channel and transmits at the same time. An important component of LBT design is the choice of an energy detection (ED) threshold, which translates into the level of sensitivity to detect the neighboring ongoing transmissions. The impact of an ED threshold on the fair coexistence can be found in (Jeon et al. [2015](#)).

Discovery Reference Signal

The discovery reference signal (DRS) was introduced in LTE Rel-12 for radio resource measurement (RRM) during the small cell OFF state. The DRS consists of synchronization signals and reference signals. Note that in the licensed carrier, synchronization signals and reference signals are always transmitted regardless of whether there is actual data transmission or not during the small cell ON state; however, in the unlicensed carrier, if there is no data transmission, then there is no

transmission at all. Therefore, the use of DRS on an LAA SCell is critical to maintain a reliable connection. Like any transmission on unlicensed carrier, the transmission of DRS is also subject to LBT.

Interlaced UL Resource Allocation

European Telecommunications Standards Institute (ETSI) specifies that the occupied channel bandwidth (OCB) shall be between 80% and 100% of the declared nominal channel bandwidth (ETSI EN 301 893 [2017](#)). To meet the OCB regulation by ETSI, the eLAA allocates user equipment (UE) with equally spaced resource blocks (RBs) spread across the entire bandwidth for UL transmission. In more detail, each interlaced resource allocation consists of ten equally spaced RBs for both 10 and 20 MHz system bandwidth.

Partial Subframes

In unlicensed spectrum, the LBT procedure can finish at any time subject to the ongoing transmission and/or the random backoff in LBT. To efficiently utilize the radio resources, the concept of a partial subframe has been introduced in Rel-13 LAA, where DL transmission can start at the first or second slot boundaries of a subframe. The DL transmission also may not end at the subframe boundary due to the limited channel occupancy time. To utilize the ending DL partial subframes with minimal specification efforts, the existing TDD special subframe structure is reused. In the current Rel-15 FeLAA WI, further DL/UL partial subframe options are to be added.

Autonomous UL Access

In the Rel-15 FeLAA WI, one of the objectives here is autonomous UL access. It was observed by multiple sources that the UL performance can be impacted when operated in unlicensed spectrum. A possible explanation can be that multiple rounds of contention are imposed before a UE can transmit on the UL. That is, LBT needs to be performed at the base station before sending the UL grant. A particular UE has to be exclusively scheduled for a given resource among associated UEs, and, finally, the LBT

by the UE has to be succeeded in order for the scheduled UL transmission to be executed. Although the detailed operation will have to be specified, the autonomous UL access has several advantages over scheduled UL access. That is, any UE can perform LBT and can transmit on the UL whenever it has data to transmit, as the UL transmission is not limited by a UL grant. The autonomous UL access will also naturally well-coexist with Wi-Fi as the UE behavior, in terms of channel access, is not different from Wi-Fi stations.

Definition

Channel modeling is the characterization of EM wave propagation in a channel, in the forms of channel impulse response and channel transfer function. The channel impulse response is the received signal that propagates through a wireless channel when the transmitted signal is an impulse, while the channel transfer function is the Fourier transformation of the channel impulse response. The channel model depends on distance, frequency, time, and propagation medium.

Historical Background

Terahertz band communication (0.1–10 THz) is envisioned as a key wireless technology to satisfy the growing demand for wireless Terabit-per-second (Tbps) links, by alleviating the spectrum scarcity. Channel modeling that characterizes the THz band is the fundamental of the designs for physical layer and data link layer in the THz communication systems. J.M. Jornet modeled the line-of-sight (LoS) THz channel in nanonetworks and detailedly analyzed the effect of molecular absorption (Jornet and Akyildiz 2010). S. Priebe introduced a stochastic spatiotemporal model has been for ultra-broadband THz indoor radio channels at 0.3 THz (Priebe and Kurner 2013). C. Han developed a ray-tracing based multipath channel for indoor scenario over 0.1–1 THz and a three-

dimensional end-to-end THz channel model (Han et al. 2015; Han and Akyildiz 2017). A hybrid channel modeling approach that combines ray tracing and statistical channel model is proposed for THz indoor channel modeling (Priebe et al. 2011).

Foundations

Terahertz band (0.1–10 THz) communication is envisioned as a key technology to support ultra-broadband wireless systems for beyond 5G. For realization of efficient wireless communication networks in the THz band, it is imperative to develop channel models which can accurately and efficiently characterize the THz spectrum peculiarities, which could be summarized as:

- Frequency-selective molecular absorption effect
- High free-space path loss
- High reflection and scattering loss
- Weak diffraction ability
- Extremely narrow beamwidth

In general, methods for channel modeling in wireless communications could be categorized as deterministic (Han et al. 2015), statistical (Priebe and Kurner 2013), and hybrid approaches (Thiel and Sarabandi 2008). The deterministic methods show high accuracy while suffering from high computational complexity. The computational complexity of statistical models is much lower than deterministic models. By the statistics of the channel properties, statistical models are adaptable to a range of propagation environment. However, the main drawback arises from the consistency with the real environment. To combine the benefits of these two methods, hybrid channel modeling balances the accuracy and low complexity (Han and Chen 2018).

Deterministic Channel Modeling

Deterministic channel models accurately model the wave propagation based on the electromagnetic wave theory. Deterministic approach is site-

specific, requiring detailed geometric information of propagation environment, properties of materials, and spatial positions of the transmitter and receiver. In general, this approach provides good consistency between the simulation results and the measurements.

Ray tracing (RT) has emerged as a popular technique for the analysis of site-specific scenarios, due to its ability to analyze very large structures with reasonable computational complexity (Han et al. 2015; Chen and Han 2018). As illustrated in Fig. 1, the radio signal transmitted from a fixed source encounters multiple objects in the environment, forming LoS, reflected, diffracted, or scattered arrival rays to the receiver. For each of these geometric paths, the RT techniques analyze the propagation of electromagnetic waves by representing the wave fronts as simple particles. In addition, the reflection, diffraction, and scattering effects are approximated by geometric optics, which becomes more accurate due to the stronger corpuscular property in the THz band. A complete and generic multipath channel model based on the RT method for the entire THz band has been established in Han et al. (2015). Furthermore, elevation plane is involved to develop a three-dimensional (3D) end-to-end channel model for the THz spectrum in Han and Akyildiz (2017)

Full-wave (FW) method, such as finite-difference time-domain (FDTD), method of

moments (MoM), and finite element method (FEM), is a numerical analysis technique that directly solves Maxwell's equations. As a main benefit, the full-wave method has the ability to resolve the small and complex scatterers and rough surface. However, this method suffers from very high computational consumption for high frequency with small wavelength and the object with complex geometry for the THz propagation.

Statistical Channel Modeling

Although deterministic methods provide accurate channel modeling results, they require detailed geometric knowledge of the propagation environment and suffer from high computational complexity. By contrast, statistical methods could be invoked to model the channel based on empirical channel measurements.

For narrowband channels, the channel is characterized by large-scale fading model and small-scale fading model. The large-scale fading model characterizes path loss and shadowing. The small-scale fading model characterizes the effect of multipaths. In small-scale fading models, the received signal is a superposition of multipaths, and therefore its magnitude and phase can be regarded to follow a certain distribution. For example, Rayleigh fading model assumes that the magnitude of a signal follows a Rayleigh distribution, which is valid in heavily built-up urban environments range with no dominant line-of-sight path.

Channel Modeling of Microscale Terahertz Communication, Fig. 1

The ray-tracing method for deterministic channel modeling

For wideband THz channels, the multipaths are resolvable in the time domain. Therefore, a *statistical impulse response model* is developed where tap delay line formulas are established to characterize the wireless propagation. This approach specifies statistical distributions on the multipath parameters including direction-of-departure/direction-of-arrival (DoD/DoA), time-of-arrival (ToA), and complex amplitudes. Furthermore, based on the clustering observations of arrival rays, a cluster-based impulse response model considers the grouping effect of the multipath components, which have closely distributed ToA and DoA/DoD (Akdeniz et al. 2014). In particular, the well-known Saleh-Valenzuela (SV) model assumes ToA of clusters and intra-cluster rays follow Poisson processes, while the arrival time for each cluster is exponentially distributed.

Hybrid Channel Modeling

On one hand, deterministic channel modeling shows high accuracy with high time and resource consumption. On the other hand, statistical channel modeling has low computational complexity with lack of accuracy. Therefore, an interesting and promising direction is to develop *hybrid methods*, by strategically combining the benefits from two or more individual approaches. Currently, there are three kinds of hybrid approaches:

- **Stochastic Scatterer-placement and RT Hybrid Approach (SSRTH).** In this approach scatterers are stochastically placed, while the multipath propagation is traced and modeled based on RT techniques in a deterministic fashion. Based on the SSRTH approach, geometry-based stochastic channel models (GSCMs) are established (Molisch 2004; Kim and Zajić 2016). In the GSCMs, scatterers are generally assigned randomly on the basis of predetermined statistical distributions. As illustrated in Fig. 2, single-bounce and multi-bounce scattering are considered, and scatterers are grouped into

clusters. Next, simplified RT are then used to track and capture the propagation of the waves. The space-time parameters are then recorded for each path to construct the complete multipath channel impulse response.

- **RT-FW Hybrid Modeling.** The principle of this method is to use FW to study regions close to complex discontinuities where ray-based solutions are not sufficiently accurate and to use RT to trace the rays out of the FW regions. This RT-FW hybrid technique is expected to provide very high accuracy in channel modeling. However, a critical challenge is to smoothly transit between the RT and full-wave methods and compute the boundary results.
- **Statistical and RT Hybrid (SRH) Approach.** Statistical impulse response channel modeling has high efficiency for characterizing the multipaths but lacks for accuracy. Therefore, a statistical and RT hybrid approach could be exploited. In particular, the dominant rays such as the LoS and the reflected are determined deterministically using RT techniques, while the other rays could be generated statistically. The main benefits include the high modeling accuracy, since the critical multipath components are computed deterministically, and low complexity since the very rich multipath effects are included using statistical modeling.

Ultra-massive MIMO Channel Modeling

Thanks to the very small wavelength at THz frequencies, hundreds and thousands of antennas can be packed in a small footprint. In the UM-MIMO channel with hundreds of antennas, the complexity increases exponentially if the deterministic channel modeling is applied to every individual sub-channel. The resulting computational and storage burden is very high (Ai et al. 2017). To address this problem, a *virtual point approximation approach* whose complexity is independent of the array size could be adopted to reduce the computing complexity. First, a point-to-point deterministic channel modeling is invoked to accurately capture the propagation between the virtual points at the transmitter and receiver as shown in Fig. 3.

Channel Modeling of Microscale Terahertz Communication, Fig. 2

Geometry-based stochastic model with single-bounce and multi-bounce scattering

Channel Modeling of Microscale Terahertz Communication, Fig. 3

The virtual point approach for deterministic UM-MIMO channel modeling

Then, this propagation model is mapped to other antenna pairs, according to the relative spatial and angular separation in the antenna array.

Statistical MIMO models can be categorized into *matrix-based models* and *reference antenna-based models*. The matrix-based models focus on characterizing the properties of the complete channel transfer matrix. On the contrary, reference antenna-based models analyze the SISO propagation model between reference transmitting and receiving antennas first. Then, the complete channel transfer matrix is generated statistically, based on the developed reference single-antenna model.

The matrix-based models characterize the UM-MIMO channel matrix, in which each

entry of the matrix represents the multipath propagation of each sub-channel in the UM-MIMO communication system. The well-known matrix-based channel models are:

- **I.i.d. Rayleigh Model.** As a simplified consideration, the entries of the channel matrix are independent and identically distributed (i.i.d.) complex Gaussian random variables in the i.i.d. Rayleigh model.
- **Kronecker Model.** This model considers the correlation between sub-channels and assumes the correlation at transmitter and receiver are separable so that the correlation matrix is a Kronecker product of two correlation matrices at transmitter and receiver, respectively.

- **Virtual Channel Representation (VCR).** It gives an angular representation of the channel matrix by sampling the rays in a beam space; each entry of the channel matrix denotes the superposition of the rays in a spatial window (You et al. 2017).
- **Weichselberger Model.** As a combination of the Kronecker and VCR models, the Weichselberger model decorrelates the channel coefficients in the eigenspace rather than the beam space. Consequently, the Weichselberger model establishes a more generic framework of UM-MIMO channels without the restrictions of uniform linear array in VCR.

The reference antenna-based models synthesize the channel matrix by applying steering vectors to the SISO statistical model corresponding to two reference antennas at Tx and Rx, respectively (Wallace and Jensen 2002). The steering vector whose entry is phase shift relative to the reference antenna is based on the DoA/DoD and array configuration. The number of multipath components, path gains, ToAs, DoAs/DoDs, and the clustering properties are quantified parameters and randomly generated for the reference sub-channel. This kind of models is also called nongeometrical stochastic model since it doesn't relate to any geometry of the physical environment. However, since ToAs and DoAs/DoDs are considered unaltered over the array, the reference antenna-based models need to be carefully revised for wideband THz communications.

SSRTH in SISO hybrid channel modeling is also suggested to develop GSCMs to characterize the UM-MIMO propagation. This approach is naturally suitable for UM-MIMO channels because the spatial-temporal properties could be well captured in practice. Furthermore, the generated statistical map is independent of mobile station (MS) and shared among multiple links and time snapshots in the UM-MIMO propagation. This enables smooth time evolution and avoids channel discontinuity. The standard spatial channel models like 3GPP SCM, WINNER, and COST2100 channel models are the representative GSCMs at microwave frequencies. Besides, a

multifocal ellipse model has been established to capture the characteristics of UM-MIMO channel including spherical wave front effect and non-stationarity over the array (Wu et al. 2015).

Key Applications

The channel modeling helps evaluate the channel performance and the designs for physical layer and data link layer in the wireless communication systems. Deterministic channel modeling can replace channel sounding which is time-consuming in some cases. The statistical channel modeling is often used in the theoretical analysis, e.g., capacity, coverage, and bit error rate (BER).

Cognitive Heterogeneous Networks

Lei Xu
Nanjing University of Science and Technology,
Nanjing, China

Synonyms

Heterogeneous wireless access medium with cognitive radio; Heterogeneous wireless networks based on cognitive radio

Definition

In cognitive heterogeneous wireless networks, the available spectrum resources for each network are dynamic and limited. It is difficult to provision quality of service (QoS) to secondary mobile terminals (MTs). Hence, integrating cognitive heterogeneous wireless networks can help to provide various classes of service to secondary MTs and to support seamless secondary MT roaming. In order to guarantee QoS for MTs, multi-homing technology can be applied, where the data stream from an MT is split into multiple sub-streams, and transmitted over multiple networks by different radio interfaces simultaneously (Xu et al. 2017a,b).

Historical Background

In the fifth generation (5G) mobile communication systems, heterogeneous wireless networks will use various wireless access technologies, e.g., macrocells providing low-to-medium rate services with a large coverage area, while microcells and Wi-Fi supporting high rate services in hotspots. In each wireless network, MTs do not always occupy all spectrum resources, and there exist vacant spectrum holes. Due to the spectrum resource scarcity, cognitive radio can be applied in each wireless network to utilize the vacant spectrum holes (Gunawardena and Zhuang 2011; Xu and Nallanathan 2016). This leads to cognitive heterogeneous wireless networks, where the coverage areas of multiple cognitive wireless networks overlap and secondary MTs can opportunistically utilize the temporary spectrum holes (Zhang et al. 2015). There are international standards, e.g., IEEE 802.11af, IEEE 802.19 TG 1, IEEE 802.22, and LTE-U, in place to promote the development of cognitive wireless networks (Xu et al. 2017c).

In cognitive heterogeneous networks, resource allocation is very important (Xu et al. 2017a,b). In Xu et al. (2017a), a call admission control algorithm based on inter-network cooperation is proposed via a Stackelberg game framework

for cognitive heterogeneous networks. The call admission control problem is subject to the variable bandwidth rate traffic, network service selection, feasible subchannel allocation, and call blocking probability. The call admission control algorithm is based on spectrum price at primary heterogeneous networks and subchannel allocation price and network selection at cognitive heterogeneous networks. In order to determine the call blocking probability, a probability upper bound of exceeding the maximum admission number for secondary MTs is analyzed based on M/M/ ∞ model. Then, the subchannel allocation price and network selection are designed via the dual decomposition method, and the vacant spectrum price is determined with Bertrand game theory. Finally, a call admission control algorithm is proposed.

In Xu et al. (2017b), a video packet scheduling framework with stochastic QoS is proposed for cognitive heterogeneous networks based on inter-network cooperation. The video packet scheduling is subject to constraints in the available energy at each call for secondary MT, the time-varying channel state information at different interfaces, the total interference power, the target call duration, and the video characteristics. The objective function maximizes the minimum lower bound of video quality. In order to solve the above video packet scheduling problem with stochastic QoS guarantee, a video packet scheduling scheme based on forward-auction theory is proposed. Then, the cumulative distribution function for video quality is analyzed. Finally, the power allocation scheme to maximize the minimization lower bound of video quality among different secondary MTs is presented.

Foundations

Consider a geographical region with $\mathcal{N} = \{1, 2, \dots, N\}$ primary wireless access networks, based on different wireless access technologies and operated by different service operators. In network n , there is a set, $\mathcal{S}_n = \{1, 2, \dots, S_n\}$, of base stations (BSs). Corresponding to network n BS s , there is a cognitive wireless

Cognitive Heterogeneous Networks, Fig. 1 Cognitive heterogeneous networks

network n BS s . The cognitive heterogeneous wireless networks are shown in Fig. 1. There is a set, $\mathcal{M} = \{1, 2, \dots, M\}$, of secondary MTs in the geographical region, and $\mathcal{M}_{ns} = \{1, 2, \dots, M_{ns}\} \in \mathcal{M}$ is a subset of the MTs, which reside in the coverage area of network n BS s . In primary network n BS s , the total spectrum is divided into K_{ns} subchannels, and each subchannel has the same bandwidth. Additionally, the transmission power at secondary BSs for downlink or at secondary MTs for uplink should be controlled to protect the transmission in primary networks according to the interference temperature model (Habachi et al. 2013). In the same cognitive network, interference mitigation is achieved by interference management schemes (Ahuja et al. 2015; Guler and Yener 2014). Using the multi-homing mechanism and multiple radio interfaces, each secondary MT can communicate with multiple secondary BSs simultaneously. In this work, we divide the spectrum into a number of subchannels. Primary networks use some subchannels, while cognitive networks utilize the vacant subchannels. The interference exists between primary networks and cognitive

networks due to the cross-channel interference, e.g., Zhang and Leung (2009) and Shaat and Bader (2012). Hence, the interference introduced by cognitive networks to primary networks should be controlled via the interference temperature model.

Consider K_{ns} time-varying subchannels licensed for primary network n BS s . The occupancy of each subchannel, $k \in \{1, 2, \dots, K_{ns}\}$, is modeled as a time-homogeneous discrete Markov process, denoted by s_{ns}^k , where $s_{ns}^k = 0$ means that the subchannel is idle and $s_{ns}^k = 1$ means that the subchannel is busy. Define α_{ns}^k (β_{ns}^k) as the probability that the licensed subchannel k at primary network n BS s changes from idle (busy) in the previous time slot to busy (idle) in the present slot. In cognitive heterogeneous networks, $1 - s_{ns}^k = 1$ indicates that the subchannel k is available for cognitive network n BS s ; otherwise $1 - s_{ns}^k = 0$ (Habachi et al. 2013). If $\rho_{nsm}^k = 1$, the subchannel k is allocated to cognitive network n BS s MT m . $\mathcal{K}_{ns}$ is the vacant subchannel set for cognitive network n BS s .

In a given service area, r , the subset of secondary MTs is $\mathcal{M}_r$. Besides its own home

network, each secondary MT can get service from other secondary BSs available at its location. Secondary MTs can be classified into two categories: network subscribers and network users. Each network subscriber uses its own home network, while each network user utilizes the other networks. Consequently, p_{nsm} is defined as a priority parameter, representing service priority for secondary network n in allocating its resources to secondary MT m via secondary BS s , where $p_{nsm} \in [0, 1)$ denotes for low-priority network users and $p_{nsm} = 1$ denotes for high-priority network subscribers. At each secondary MT, single-network service and multi-homing service are considered. The subset of secondary MTs using single-network service in the service area r is $\mathcal{M}_{1r}$, while the subset of secondary MTs using multi-homing service is $\mathcal{M}_{2r}$. $\mathcal{S}_r$ is the subset of all secondary BSs in the service area r . The set of secondary MTs in cognitive network n BS s , including MTs using either multi-homing service or single-network service, is denoted by $\mathcal{M}_{ns}$.

If secondary MT m uses single-network service in area r , the constraint is $\sum_{n \in \mathcal{N}} \sum_{s \in \mathcal{S}_n} x_{nsm} = 1$, $m \in \mathcal{M}_{1r}$, $r \in \mathbf{R}$. x_{nsm} is a binary assignment variable, e.g., if secondary MT m communicates with cognitive network n BS s , $x_{nsm} = 1$; otherwise $x_{nsm} = 0$. $\mathbf{R}$ is the service area set. If secondary MT m uses multi-homing network service in area r and cognitive network n BS s serves in the service area r , the constraint is $x_{nsm} = 1$, $m \in \mathcal{M}_{2r}$, $r \in \mathbf{R}$.

Consider the video traffic at each secondary MT. In a geographic area, the video call arrivals are modeled as a Poisson process (Ghosh et al. 2011). Specially, in service area r , the arrival process for both new and handoff video calls is modeled by a Poisson process with arrival rate v_r . Additionally, the video call duration follows exponential distribution. The video call is variable bandwidth rate (VBR) traffic. For secondary MT m , a VBR call requires a bandwidth allocation within a minimum value, $B_m^{\min}$, and a maximum value, $B_m^{\max}$. In a given service area, if there are sufficient bandwidth resources, the VBR call will obtain the maximum required bandwidth, $B_m^{\max}$. When all secondary BSs reach their

capacity limitation, the bandwidth allocation for each VBR call is degraded toward the minimum required bandwidth, $B_m^{\min}$ (Xu et al. 2014).

Key Applications

Cognitive heterogeneous networks are fundamental network architecture in future wireless communication systems, e.g., 5G.

Definitions

Cognitive radio sensor network (CRSN) is a kind of wireless sensor networks where sensor nodes and sink nodes are equipped with cognitive radio modules to opportunistically access spatiotemporally available channels to transmit sensed data (Akan et al. 2009). Different from traditional cognitive radio network, cognitive radio sensor network is more sensitive to the energy consumption in channel sensing and switching, which motivates the study of spectrum management focusing on improving the energy efficiency of power-limited sensor nodes.

Historical Background

Both of the concept proposals of wireless sensor network (WSN) and cognitive radio (CR) can be dated back to the 1990s or earlier (Mitola and Maguire 1999; Akyildiz et al. 2002). A WSN typically comprises a large number of battery-powered sensor nodes deployed in an interested area to perform environmental sensing and information converting and processing and then transmit their sensed data to sink nodes for further usage. With the low-cost and self-organized WSNs, humans are enabled to transfer various information data from the physical world to the cyber world in an

efficient manner and thereby promote the great fusion of cyber physical systems. Due to the power and cost limits of sensor nodes, short-range and low-power communication protocols operating on the unlicensed spectrum, such as Zigbee and Bluetooth, are widely adopted as the communication technologies for WSN to guarantee the energy efficiency of sensor nodes. However, with the explosion of mobile devices and services, the spectrum resources for wireless communications become increasingly scarce, making the data collection of WSNs face significant interference caused by nearby wireless applications. Thus, plenty of research efforts have been paid on addressing the energy-scarcity and spectrum-scarcity problems during recent years.

Cognitive radio has been proposed as a promising solution for alleviating spectrum-scarcity problem. It was first proposed by Joseph Mitola III in a seminar at KTH (the Royal Institute of Technology in Stockholm) in 1998 and published in 1999 (Mitola and Maguire 1999). The key idea of CR is to enable mobile devices to intelligently sense the ambient radio environment and dynamically configure the radio operation parameters to access the best vacant channel for opportunistic data transmission. After a few years' development, CR has experienced a big step forward from theory to practice. In Oct. 2004, the Institute of Electrical and Electronic Engineers (IEEE) initialized a special group, named IEEE 802.22 work group, to develop the international standards for CR. The standards were published in July 2011 and attracted a large number of CR test-beds and products in the past years.

The concept of CRSN was first proposed by Prof. Ozgur B. Akan in 2009 (Akan et al. 2009), with the aim of applying CR into WSN to address the spectrum-scarcity problem of WSN. As sensor nodes are sensitive to the energy consumption of spectrum sensing and channel switching, a key challenge of CRSN is to provide energy-efficient spectrum management strategies, including spectrum sensing, dynamic channel accessing, shar-

ing, and allocation, for guaranteeing the energy efficiency of the network.

Foundations

The architecture of CRSN is shown in Fig. 1, where a large number of distributed sensor nodes equipped with cognitive radio modules can opportunistically access vacant licensed channels to transmit their sensed data to the sink node via a multihop manner (Akan et al. 2009). The sink may also be equipped with CR capabilities to receive data via different channels. To efficiently manage the dynamic channel access in CRSN, there should be a default control channel for communicating the control information and coordinating the whole process.

Figure 2 shows the hardware architecture of a cognitive radio sensor node (Akan et al. 2009). As shown in the figure, the main difference between the hardware structure of a classical sensor node and a CR sensor node is the cognitive radio transceiver. The cognitive radio unit enables the sensor nodes to dynamically adapt their communication parameters, such as carrier frequency, transmission power, and modulation. Cognitive radio sensor nodes also inherit the limitations of conventional sensor nodes in terms of power, communication, processing, and memory resources, which consequently restrict the features of cognitive radio.

Compared to traditional WSNs with fixed spectrum allocation, CRSN can benefit from many advantages brought by CR technology. Opportunistic channel access enables CRSN to achieve timely and bursty data transmission when the unlicensed spectrum is crowded. It also can improve the energy efficiency of data collection by avoiding data collision and retransmission over the highly interfered unlicensed spectrum. In addition, dynamic spectrum management significantly contributes to the efficient coexistence of spatially overlapping sensor networks or other

Cognitive Radio Sensor Networks, Fig. 1 The architecture of CRSN

Cognitive Radio Sensor Networks, Fig. 2 The hardware architecture of a cognitive radio sensor node

wireless applications in terms of communication performance and resource utilization.

Key Applications

CRSN can be widely applied in various scenarios where many overlapping wireless applications coexist making the unlicensed spectrum crowded. It can be well exploited to provide a spectrum- and energy-efficient data sensing and collection solution for delay-sensitive and bursty traffic applications. Some representative applications can be referred to E-healthcare systems, indoor multimedia sensing, and smart city applications.

Future Directions

As an emerging solution to address the spectrum scarcity problem in the IoT area, CRSN is still in its infancy and faces many obstacles hindering the flourish of its applications. Listed below are some potential future research directions:

- Distributed Spectrum Resource Management for Large-Scale CRSNs:* In large-scale CRSNs, some sensor nodes have to forward a significant amount of sensed data to the sink node. In order to improve the network lifetime and performance, multiple sink nodes or mobile sink nodes are usually deployed, accompanying with dynamic routing schemes, for balanced energy consumption. It consequently makes the spectrum resource management increasingly complicated and challenging. For large-scale CRSNs, centralized mechanisms/algorithms can no longer meet the QoS requirements in terms of processing delay and scalability. However, from the spectrum management perspective, centralized mechanisms/algorithms can provide more accurate control for spectrum sensing and accessing than distributed solutions (Ren et al. 2016a,b). Therefore, how to design efficient distributed spectrum
- resource management for addressing this dilemma in large-scale CRSNs becomes an challenging but meaningful research direction.
- Cross-layer Design for Opportunistic Spectrum Access:* Cross-layer design has been proved as an effective solution to improve the network performance during the past decade. The core idea is to maintain the functionalities associated with the original layers but to allow coordination, interaction, and joint optimization of protocols crossing different layers. There have been a large number of existing works focusing on cross-layer design for both wired and wireless networks. However, since most of them are proposed for the networks with specific communication channels, they are not suitable for CRSNs with opportunistic spectrum access. It motivates researchers to devote more attention on the cross-layer design for CRSNs to improve the overall network performance.
- RF Energy Harvesting and Transfer in CRSNs:* The flourish of WSN and CRSN applications is highly impeded by the limited energy supply of battery-powered sensor nodes. Thus, an emerging energy harvesting technology enables sensor nodes to absorb energy from ambient RF signals, which shows strong potentials to power future CRSNs (Ren et al. 2018). By RF energy harvesting, sensor nodes have no need to add additional energy harvesting devices, such as solar photovoltaics and wind turbines, to get recharged. Meanwhile, since CRSN has the capability of cognitively deciding to access different spectrum bands, it can sense a channel with the strongest RF signals as the energy harvesting channel and let the charging sensor nodes access to improve the charging efficiency (Zhang et al. 2017). Furthermore, with such a promising technology, sensor nodes can transfer energy among each other via RF signals to alleviate the unbalanced energy consumption in CRSNs. Therefore, CR and RF energy harvesting can be viewed as two complementary technologies and arise a number of interesting research topics in RF-powered CRSN applications.

Definition

Cognitive Radio-based Non-orthogonal Multiple Access (CR-NOMA) is a derivation of NOMA. In CR-NOMA, a user with bad channel condition is viewed as the primary user (PU), while a user with good channel condition is regarded as the secondary user (SU), which is squeezed into the spectrum occupied by PU (Ding et al. 2016). CR-NOMA opportunistically serves one user on the condition that other users' Quality of Service (QoS) is guaranteed.

Historical Background

The advent of CR-NOMA is driven by the advantages of NOMA and CR. Recently, NOMA has attracted increasing attention because of its high spectral utilization. At the transmitter side, multiple users' signals can be transmitted simultaneously in time domain, frequency domain, or code domain by utilizing power domain multiplexing. At the receiver side, the multiplexed signals can be separated by using Successive Interference Cancellation (SIC). Thus, the resource block (time, frequency or code) is not solely occupied by one user but shared by multiple users. As an emerging technology to improve wireless spectrum utilization, CR has also attracted extensive attention because it allows SU opportunistically accessing to the spectrum initially licensed to PU (Lv et al. 2018). Intuitively, the combination of CR with NOMA can further improve radio resource utilization.

The radio resource management departments in different countries have something in common on wireless spectrum management. Specifically, the wireless spectrum allocation scheme in different countries often adopts the “fixed allocation” principle (Zhou et al. 2017), based on which the allowable spectrum is divided into several segments. Each segment is assigned to a user (or a group of users) and other users have no right to use it. The corresponding spectrum segment is called licensed band, while the user (or the

group of users) using the licensed band is called licensed user.

Since the popularization of smart terminals and the surge of mobile traffic stimulate the evolution of communications technology, as a kind of nonrenewable resources, the spectrum resource available is more scarce than ever before (Agiwal et al. 2016). A survey on spectrum usage from Federal Communications Commission (FCC) has pointed out that a large number of spectrum resources have different degrees of idleness in time and space dimensions even in some crowded bands (Kolodzy and Avoidance 2002). This is because only a small portion of spectrum is used frequently based on the “fixed allocation” principle (Zhou et al. 2017). In order to improve the utilization of the licensed spectrum as much as possible, various multiplexing techniques such as Frequency Division Multiple Access (FDMA), Time Division Multiple Access (TDMA), Code Division Multiple Access (CDMA), and Multiple-Input Multiple-Output (MIMO) are put forward to support more users at the limited band (Wang and Liu 2011). However, they cannot fundamentally deal with the scarcity of spectrum resources caused by the “fixed allocation” principle.

In 1999, the concept of CR was first proposed by Dr. Mitola (Mitola and Maguire 1999). Then, Haykin defined CR from the communication point of view (Haykin 2005), pointing out that it is a form of intelligent wireless communication systems. He said that CR can automatically sense the usage of surrounding spectrum and use the idle spectrum without affecting the normal communications of licensed user. Generally speaking, the licensed user is referred to as PU, while the unlicensed user is known as SU or cognitive user. According to the definition of CR, SU should possess the abilities of spectrum sensing and reconfiguration simultaneously. On one hand, SU needs to detect whether there exists idle spectrum available. On the other hand, SU must hand over the spectrum immediately when PU needs to reuse it. It also needs to adjust the software/hardware parameters and working parameters according to the result of spectrum sensing.

So far, CR has been identified as a promising solution to spectrum scarcity and low spectrum utilization. Based on the key idea of Dynamic Spectrum Access (DSA), CR allows opportunistically utilizing idle spectrum without disturbing PU. So, multiple users or services can share the same spectrum segment, and then achieve the goal to avoid the high cost of spectrum resetting and improve spectrum utilization (Hu et al. 2018).

On account of the advantages of CR, it seems to be the perfect answer to address the challenges and requirements that the Fifth Generation (5G) of mobile communication systems poses (Tragos et al. 2013; Zhou et al. 2017).

In order to further ensure the sustainability of mobile communication services over the next decade, new technical solutions that can respond to future challenges and requirements need to be pondered and developed (Boccardi et al. 2014). For future Radio Access (RA) in the 2020 era, the mobile data traffic has been anticipated to undergo an exponential increase, e.g., at least 1000-fold in the 2020s compared with 2015. Therefore, the significant gains in the system capacity/efficiency and Quality of Experience (QoE) for users are required in the 2020 era. In cellular mobile communications, the design of RA technology is one important aspect to improve the system capacity in a cost-effective manner. In particular, the multiple access is a key element of RA technology. For example, in the Third Generation (3G) mobile communication systems, Wideband-CDMA (W-CDMA) and CDMA2000 and Direct Sequence-CDMA (DS-CDMA) are used whose receiver is based on simple single-user detection by using the Rake receiver. Orthogonal Multiple Access (OMA) based on Orthogonal Frequency Division Multiple Access (OFDMA) or Single Carrier-FDMA (SC-FDMA) is adopted in the 3.9G and 4G mobile communication systems (Razavi et al. 2017) such as Long Term Evolution (LTE) and LTE-Advanced (LTE-A) (Han et al. 2014; Higuchi and Kishiyama 2013). OMA is a reasonable and competent choice for achieving good system-level throughput performance in packet-domain services. However, the further enhancements in system efficiency and QoE,

especially at cell edge, are required in the 5G era. To accommodate such demands, NOMA has appeared as a promising candidate of multiple access scheme for the further enhancements of system performance. NOMA achieves user multiplexing typically in power domain that was not sufficiently utilized in previous generations of mobile communication systems. In NOMA, multiple users are multiplexed in power domain at the transmitter side and de-multiplexed at the receiver side by using SIC (Haykin 2005; Hu et al. 2018). From an information-theoretic perspective, NOMA with SIC is an optimal multiple access scheme according to the achievable multiuser capacity region (Tragos et al. 2013; Zhou et al. 2017; Rawat et al. 2016; Boccardi et al. 2014; Agiwal et al. 2016; Kolodzy and Avoidance 2002; Razavi et al. 2017; Higuchi and Kishiyama 2013). Compared with OMA, NOMA can contribute to the simultaneous enhancement of system efficiency and cell-edge user's experience. This is of particular importance to the future cellular systems where the channel conditions vary significantly among users due to the near-far effect.

Combining the advantages of CR and NOMA, CR-NOMA not only allows dynamically accessing to idle spectrum, but has the potential to accommodate more users (i.e., more SUs and/or more PUs) transmitting signals simultaneously according to NOMA principle, improving spectrum utilization, system throughput, and the fairness among users (Lv et al. 2018). These features are highly qualified for the applications oriented to 5G, such as Internet of Things (IoT) and low-power Machine-Type Communications (MTCs).

Foundations

CR is also called smart radio which has the abilities of intelligent learning and interaction with surrounding environment. Its core idea is to achieve DSA and spectrum sharing by spectrum sensing and learning ability. In CR, SU dynamically searches for "spectrum hole." When PU completes communications, SU should immediately detect the spectrum initially licensed by

PU, and then communicate on the idle spectrum. Whenever PU restarts communications, its signal should be detected by SU with an extremely high probability. Then, SU must release the spectrum or reduce transmit power to guarantee that there is no interference with PU. The reaction time of SU has strict regulations whose standard setting is one of the major works of CR.

In fact, spectrum utilization can be further improved because CR mainly focuses on the idle spectrum detection and the allocation to only one user (PU or SU), with less attention to the high-efficiency access scheme. For example, the traditional CR does not support the simultaneous communications between PU and SU on the same spectrum segment. Therefore, higher spectrum utilization is anticipated if the coexistence of PU and SU is allowed (Zheng et al. 2010). By introducing NOMA into CR, the opportunity of SU to access to the spectrum which is licensed to PU can be increased. Moreover, system throughput can be largely improved because the same spectrum is more efficiently utilized.

Though many NOMA schemes have been proposed for the future 5G RA techniques, such as Power Domain NOMA (PD-NOMA), Sparse Code Multiple Access (SCMA), Pattern Division Multiple Access (PDMA), Lattice Partition Multiple Access (LPMA), and Interleave Division Multiple Access (IDMA) (Ding et al. 2017), they are designed in the light of the similar concept that multiple users can be served in one orthogonal block (time slot, OFDMA subcarrier, or spreading code). As a typical case, PD-NOMA is elaborated.

In power domain, NOMA is realized by allocating different power levels to different users (Islam et al. 2016). Next, a simple example is introduced to elaborate the principle of NOMA. A Base Station (BS) serves two single-antenna users simultaneously on the same subcarrier. Here, we suppose that the weak user with bad channel condition (i.e., the user may be at cell edge) is PU and the strong user with good channel condition is SU (i.e., the user may be close to BS). We hope the QoE of PU can be satisfied. The channels of PU and SU are denoted by h_1 and h_2 . BS superimposes their signals by allocating

different power coefficients which are denoted by α_1 and α_2 . The key idea of NOMA is to allocate more power to PU (Zabetian et al. 2017). That means, if $|h_1| < |h_2|$, then $\alpha_1 > \alpha_2$ with $\alpha_1^2 + \alpha_2^2 = 1$. Thus, the signal of PU is strong at SU. In other words, SU receives a strong interference from PU because of more transmit power allocated to PU. In contrast, PU is quite less influenced by the inference from SU because of less transmit power allocated to SU. Therefore, PU decodes its own signal directly by treating the signal from SU as noise, and the achievable rate of PU is expressed as

$$R_1 = \log_2 \left(1 + \frac{|h_1|^2 \alpha_1^2}{|h_1|^2 \alpha_2^2 + \sigma^2} \right),$$

where σ^2 is the normalized noise variance. Then, SU performs SIC. Specifically, it decodes the signal of PU, and then subtracts this signal from its observation. Finally, it decodes its own signal. The achievable rate of SU is formulated as

$$R_2 = \log_2 \left(1 + \frac{|h_2|^2 \alpha_2^2}{\sigma^2} \right).$$

In contrast, for the case of two users in OMA, we suppose the allowable spectrum is divided into two parts denoted by β_1 and β_2 , while $\beta_1 + \beta_2 = 1$. For simplicity, we only consider the unit spectrum (1 Hz). Thus, the achievable rate of PU and SU are expressed as

$$\begin{aligned} R_1 &= \beta_1 \log_2 \left(1 + \frac{\alpha_1^2 |h_1|^2}{\sigma^2} \right) \\ R_2 &= \beta_2 \log_2 \left(1 + \frac{\alpha_2^2 |h_2|^2}{\sigma^2} \right) \end{aligned}$$

Since NOMA adjusts the users' throughputs by changing their power allocation ratio, the throughput and fairness between these two users can be improved and optimized. On the condition that the two users have different Signal-to-Noise Ratios (SNRs), it can be easily proved that the throughput based on NOMA is higher than that based on OMA. In other words, NOMA is more effective in dealing with different SNRs.

NOMA allocates more power to PU with bad channel condition and less power to SU with good channel condition to guarantee the fairness between PU and SU. However, it cannot strictly provide the targeted QoS to PU. Fortunately, CR-NOMA is able to deal with this situation.

CR-NOMA aims at treating NOMA as a special case of CR, where the power allocations to PU and SU conditioned on their predefined QoS requirements (Ding et al. 2016). For example, in the downlink transmission with NOMA scheme, enough power should be allocated to PU with bad channel condition to strictly satisfy a data rate threshold as follows

$$\log_2 \left(1 + \frac{|h_1|^2 \alpha_1^2}{|h_1|^2 \alpha_2^2 + \frac{1}{\text{SNR}}} \right) \geq R_T$$

where R_T denotes the target data rate. If there is any power left afterwards, SU can be served by the remaining power. CR-NOMA guarantees that PU will always be served by sufficient power to satisfy its QoS requirements. By using CR-NOMA, not only PU can be served with its targeted QoS, but also SU can be allowed to use this subcarrier. Therefore, the achievable system throughput can be increased on the premise of fairness between PU and SU.

Key Applications

So far, CR has been applied to many fields. In the civil field, CR is adopted in Wireless Regional Area Network (WRAN), Adaptive Heuristic for Opponent Classification (AdHoc) network, Ultra-Wideband (UWB) system, Wireless Local Area Network (WLAN), Mesh network, and MIMO system. In the military field, CR can also be adopted since it can improve system throughput, spectrum management efficiency, electronic countermeasures, and system interconnection and interoperability capability.

As a multiple access technology in power domain, NOMA can greatly improve spectrum utilization and device access capability. It can obtain robust system gain without relying

on the Channel Quality Indicator (CQI) or Channel State Information (CSI). Furthermore, it can reduce the network transmission delay and terminal consumption by simplifying transmission scheduling. The combination of NOMA and other communications technologies can further improve the system performance.

In 5G networks, there are many typical performance requirements, such as high system throughput, low latency, large-scale connections, high spectrum management efficiency, and so on. As the combinational technology of NOMA and CR, CR-NOMA can evidently improve a certain metric on the premise of guaranteeing other metrics. Because CR-NOMA integrates the advantages of CR and NOMA, it can be applied to most of application fields of NOMA and CR, especially in the 5G networks. CR-NOMA can provide services for multiple users at the same time and provide efficient spectrum utilization. Recently, the industry is occupied in the effort to incorporate CR-NOMA into 5G network. The advances of LTE-A and digital television standards also show that CR-NOMA will become a part of the future generation of wireless networks.

Future Directions

As a new form of non-orthogonal access technology, CR-NOMA is receiving widespread attention. A lot of research on CR-NOMA and its derivative techniques oriented to 5G system is in progress. We only list some possible directions and challenges face by CR-NOMA in the future, including the following:

- CR-NOMA needs to further split the difference between the system throughput and the cell-edge user throughput. To deal with it, the more effective power allocation and user matching algorithms are necessary.
- The combination of CR-NOMA and MIMO technology can support more users at the same time, and further improve the system throughput. Therefore, the joint design of precoding

and power allocation should be further studied.

- Since cooperative relaying technique can improve the signal reception, it can be applied to CR-NOMA to further improve the communication performance of PU. However, this work is still in its infancy and needs further investigation.

[Distributed beamforming in wireless sensor networks](#)

Definitions

Collaborative Beamforming (CB) in Wireless Sensor Networks (WSNs) is a transmission technique of improving the energy efficiency and signal gain between collaborating nodes and the base station (BS) in one-hop transmission. The collaborative nodes in CB use the way of cooperative communication to form the high gain and directivity in the direction of the intended BS or sink node.

Historical Background

WSNs have been playing an increasing role in many application areas, such as agriculture, industry, environmental monitoring, and so on. From another point of view, due to the limited energy and transmission distance for the sensor node in WSNs, many research studies focus on the design of method or scheme for improving the energy efficiency and the network performance. The purpose is to reduce the energy consumption and prolong the network lifetime. In recent years, the CB provides a promising technique in increasing the transmission distance and improving the energy efficiency for WSNs. Ochiai et al. (2004) are the first present the concept of CB. The authors mainly focus on the analysis of the beampattern performance for the collaborative nodes randomly located at the given areas and the feasibility of CB communication in WSNs. In the same year, Barriac et al. (2004) proposed a similar concept called distributed beamforming in WSNs. This literature mainly discussed the realizability of the phase and frequency synchronization. Based on the feasibility of achieving phase synchronization, many works on CB in WSN have been proposed. These research studies can be divided into two classes, i.e., the statistical analysis of beampattern and the performance optimization of beampattern, respectively.

In terms of the statistical analysis of beampattern, these works focus on the analysis of beampattern performance for different random

distributions of sensor nodes. Ochiai et al. (2005) are the first to present the statistical performance of the CB beampattern for the uniformly distributed sensor nodes over a disk. Some conclusions can be drawn from the analyzed results, e.g., the narrow mainlobe can be obtained as the number of sensor nodes in the large disk increases. Also, when the deployment of sensor nodes is sparse enough, the directivity can approach N . Furthermore, Ahmed and Vorobyov (2009) analyze the performance of the Gaussian distribution of sensor nodes. The results show that the Gaussian distributed nodes have a lower directivity.

However, achieving the performance requires a large number of sensor nodes deploying at the disk areas, which is unrealistic for the practical WSN applications. Therefore, in order to improve the beampattern performance, the beampattern optimization of CB in WSN has attracted increasing attentions in recent years. The objectives of beampattern optimization mainly include minimizing the sidelobe level (Malik et al. 2009), maximizing the directivity (Jayaprakasam et al. 2014), minimizing the total power (Schedler and Kuehn 2014), and maximizing the network lifetime (Ahmed and Vorobyov 2011). Most of literatures focus on the minimizing sidelobes. The methods of minimizing sidelobes include the minimization of peak sidelobe (PSL) and sidelobe control in the direction of several unintended BS. Generally, the above optimization objectives are achieved via the coefficient perturbation and node selection. The coefficient refers to the amplitude of signal or the power transmission signal. The node selection needs to use the optimization method to select a subset of nodes from N collaborative nodes. Since the optimization problem is nonconvex, the heuristic algorithms are used for optimizing the beampattern of CB in WSN, such as particle swarm algorithm (PSO) (Malik et al. 2009), genetic algorithm (GA) (Wong et al. 2012), and so on. Moreover, due to high computational complexity of heuristic algorithms, Chen et al. (2016) proposed a node selection algorithm with a lower complexity, which is achieved based on cross entropy optimization (CEO).

The corresponding decentralized implementation of CEO is also presented. As the mentioned in Jayaprakasam et al. (2017), the future works need to consider the more practical characteristics, such as the nonideal antenna and channel, nonperfect synchronization, etc.

Foundations

The beampattern analysis of CB in WSNs needs the foundation of the knowledge of random antenna array. The more detailed description is given in Lo (1964) and Ochiai et al. (2005). To facilitate the understanding of CB in WSNs, some corresponding definitions and notions in CB need to be explained. The specific description is presented in (Fig. 1).

Array Factor Model: The array factor model is critical for the analysis of beampattern for CB in WSNs. Before presenting the array factor model, some assumptions need to be given. In WSNs, the N collaborating nodes are randomly deployed at circle areas and the polar coordinates are used to denote the location of each node. The corresponding coordinate of the k_{th} node is denoted by (r_k, ψ_k) . Similarly, the coordinates of the received BS is denoted by (A, ϕ_0, θ_0) . Furthermore, each node has location information of all nodes and

Collaborative Beamforming in Wireless Sensor Networks, Fig. 1 Collaborative beamforming scenario in WSNs

the perfect synchronization. The two dimensional model is considered, i.e., the sensor nodes and BS are on the same plane. Therefore, $\theta = \theta_0 = \frac{\pi}{2}$. Based on these assumptions, the array factor for the N nodes in WSNs can be written as

$$AF(\phi, \theta | \mathbf{r}) = \frac{1}{N} \sum_{k=1}^N e^{j\psi_k} e^{j\frac{2\pi}{\lambda} d_k(\phi, \theta)} \quad (1)$$

where $d_k(\phi, \theta) = \sqrt{(A^2 + r_k^2 - 2r_k A \sin\theta \sin(\phi - \psi_k))}$ is the distance between the k_{th} collaborating node and the received BS, and ψ_k is the initial phase of collaborating node $k \in 1, 2, \dots, N$. The initial phase can be obtained by the closed-loop method and the open-loop method (Ochiai et al. 2005). When the initial phase ψ_k is equal to $-\frac{2\pi}{\lambda} d_k(\phi, \theta)$, the maximum amplitude in direction of the intended BS (A, ϕ_0, θ_0) is obtained (As shown in Fig. 2).

Mainlobe and Sidelobes: The lobe including the maximum radiated power in beam pattern of CB is referred to the mainlobe. Moreover, the lobes that remove the main lobe in beam pattern of CB are sidelobes. In Fig. 2, the regions of the mainlobe and sidelobes are given.

Far-field Beam pattern: When the condition of far-field $A \gg r_k$ holds, i.e., the distance between the k_{th} node and BS is much larger than the r_k , the array factor is approximated by

$$AF(\phi, \theta | \mathbf{r}) = \frac{1}{N} \sum_{k=1}^N e^{j\frac{4\pi}{\lambda} r_k \left[\sin\left(\psi_k - \frac{\phi}{2}\right) \sin\frac{\phi}{2} \right]} \quad (2)$$

If $z_k = r_k \sin\left(\psi_k - \frac{\phi}{2}\right)$, the $AF(\phi | \mathbf{r}, \theta) = AF(\theta | \mathbf{z})$. The far-field beam pattern can be defined as $P(\theta | \mathbf{z}) = |AF(\theta | \mathbf{z})|^2$.

Average Beam pattern: The average beam pattern is defined by the statistical average of the far-field beam pattern, i.e., $P_{av}(\theta) = E_z\{P(\theta | \mathbf{z})\}$, where $\mathbf{z} = [z_1, z_2, \dots, z_N] \in (-\infty, +\infty)^N$.

Directivity: The directivity denotes the concentration level of radiated energy in the intended direction.

Synchronization: The perfect synchronization is important for CB communication in WSNs. The collaborative nodes compensate the phase offset such that the intended BS of receiving the signal from collaborative nodes can achieve the high gain. From Eq. (1), the initial phase provides the phase offset to implement CB. The methods of achieving synchronization are performed by the bit feedback from the intended BS. The process of bit feedback generally includes the following steps. First, each collaborating sensor node sends a test signal to the BS. When the BS receives the signal, the BS will broadcast the feedback information, such as channel state and signal amplitude, to all collaborative nodes. Finally, each collaborative node updates the coef-

Collaborative Beamforming in Wireless Sensor Networks, Fig. 2

Mainlobe and sidelobes in Beam pattern

ficient perturbation to achieve the synchronization. The more detailed studies of synchronization are given in Jayaprakasam et al. (2017).

Key Application

The CB technique in WSNs provides a lower energy consumption and longer transmission range, which has been widely used in various monitoring applications, such as agriculture, environment, volcano hazard monitoring. Specially, when the distance between sensor nodes and the BS is longer than 5 km Felici-Castell et al. (2017), CB in WSNs can achieve the long distance communication and power gain. In the future, as the improvement of both theoretical methods and practical implementation technologies, CB in WSNs will provide more the effective solution for more monitoring applications which require higher energy efficiency and longer distance communication.

Collaborative Multipath Transmission

Yuanlong Cao, Li Zeng, Qinghua Liu, Gang Lei, Hao Wang, and Minghe Huang
Jiangxi Normal University, Nan Chang, China

Synonyms

Multiple network paths; Multipath transport protocol

Definitions

Multiple network paths can be established by the protocols on different network stack layers and can be used to send traffic data, enhance the connection reliability, achieve load balancing, etc.

Multipath transmission technology allows a network device equipped with multiple network interfaces (a.k.a a “multi-homed” device) to use multiple network paths for data transmission.

Collaborative multipath transmission is a promising technology toward collaboration multipathing by involving the full cooperation of all network elements (e.g., network nodes and protocol stacks) in multipath transmission.

Historical Background

In the past several years, wireless networking technologies have undergone a rapid development. Significant advances in these wireless technologies have enabled today’s network devices to be equipped with multiple network interfaces (Sinky et al. 2019; Elgabli et al. 2019). Such multi-homed devices can exploit the connection diversity of multiple paths to possibly guarantee data transmission performance and protect against the single-path failures, supported by the emerging multipath transmission protocols (Li et al. 2016). Figure 1 shows a typical multipath transmission scenario which involves

two multi-homed devices (server and mobile device 4 (MD4)) that connect to each other through two paths (1 and 2). Such multipath transmission way can enable high-level quality of service provisioning for data delivery.

Current multipath transmission deployments exploit multiple paths to provide high-level transmission performance in two ways: (i) *Primary-alternative single-path transfer*. In this situation, the sender selects one path as the primary path, which is used for traffic data transmission. If the primary path becomes unavailable, the sender selects one of the alternate paths to perform continuous transmission of that data. (ii) *Concurrent multipath transfer*. In this situation the sender makes use of multiple network interfaces to perform concurrent transfer of data over all the available paths in the transmission session, achieving load balancing and increasing the throughput (goodput) performance.

Due to its attractive multipathing feature, multipath transmission technologies attract considerable attention and have resulted in many relevant Internet drafts, research publications, and industry applications. On the aspect of standardization, several IEEE and IETF working groups have concentrated their efforts on the standardization of multipath on different TCP/IP protocol stack layers (Lei et al. 2018; Devetak and Kapoor 2017; Stewart 2007; Ford et al. 2013; 802.1AX 2008; IEEE 802.1aq 2012; Eastlake et al. 2008, 2014). For example, the IETF has released two promising transport layer multipath transmission protocols, Stream Control Transmission Protocol (SCTP) (Stewart 2007) and Multipath Transmission Control Protocol (MPTCP) (Ford et al. 2013), in order to enable the concurrent use of multiple IP addresses/interfaces toward transport layer multipathing.

On the aspect of industry applications, several big high-tech companies are investing considerable amounts of research resources in the multipath technologies. For example, Samsung is dedicated to developing and deploying the Download Booster (Samsung 2018), which allows a multi-homed device to speed up the download of large files by using both the Wi-Fi and cellular connections simultaneously. Apple

Collaborative Multipath Transmission, Fig. 1 A typical multipath communication scenario between two multi-homed devices

Corporation applies the MPTCP technology to the iOS-based products (Apple 2018) in order to improve devices' network reliability and performance. Tessares company (Detal et al. 2017) tried to combine xDSL with LTE to create hybrid access networks, by using the promising MPTCP technology.

On the aspect of academic research, thousands of peer-reviewed publications revolving around multipath transmission technologies have been released in the past few years, covering the application, transport, network, data link, and physical layers of the TCP/IP protocol stack and involving a wide range of aspects such as packet scheduling, congestion control, resource pooling, fairness, energy saving, packet reordering, partially reliable extension, potentially failed path detection, and multipath usage. More recently, an increasing number of researchers are actively developing the promising collaborative multipath transmission technologies in order to break through the default TCP/IP stack framework and the rigid sender-centric control design.

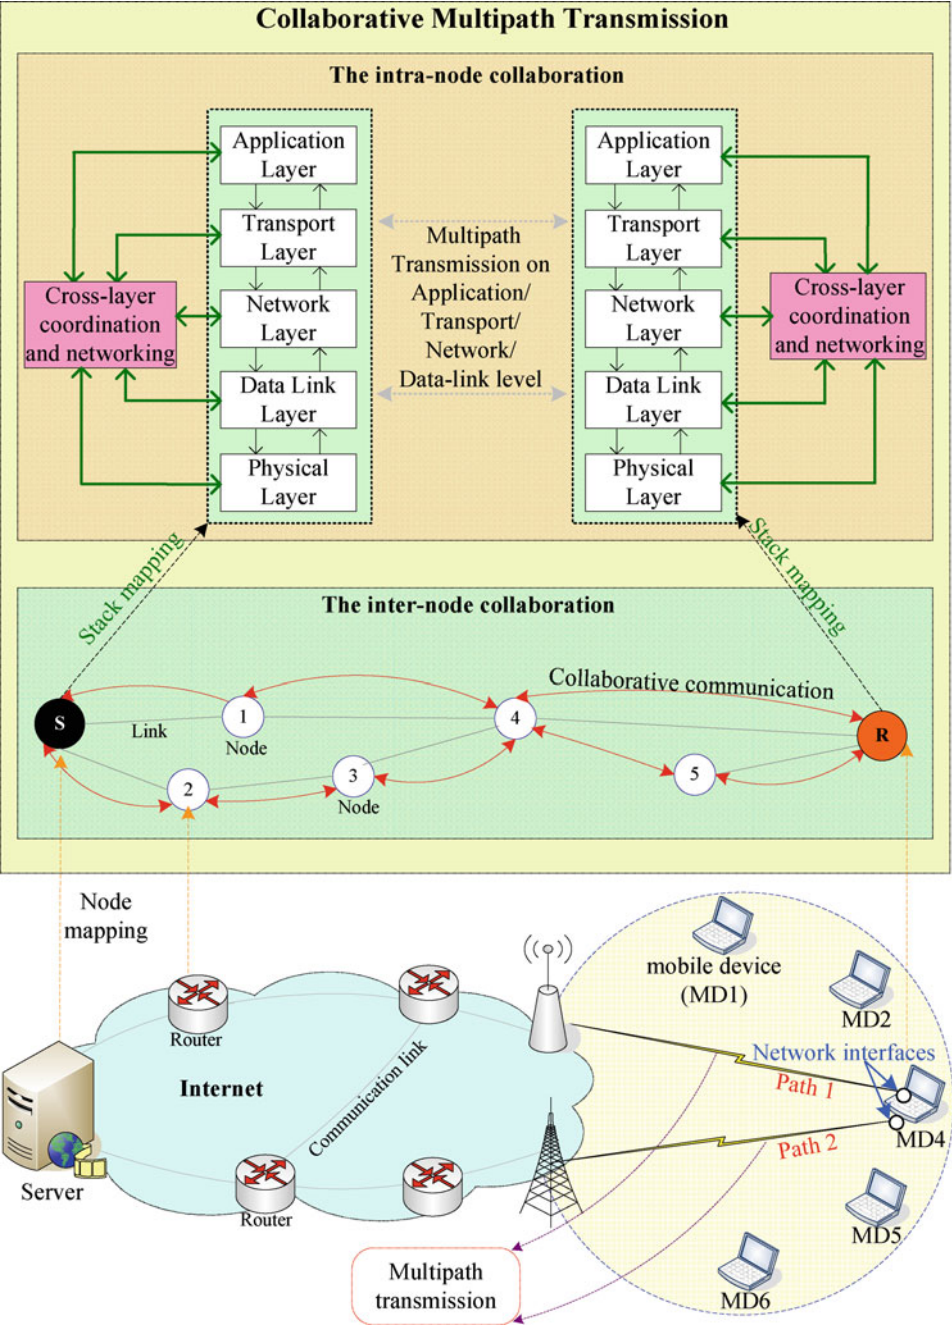

Key Points

Collaborative multipath transmission technologies can be categorized into two types: *internode collaborative multipath transmission technologies* and *intra-node collaborative multipath transmission technologies*. *Internode*

collaborative multipath transmission in general means the collaboration among various network nodes in multipath transmission (Cao et al. 2014, 2016a,b). *Intra-node collaborative multipath transmission* here refers to the cross-layer collaboration among various network protocol stacks of one node for efficient multipath transmission (Lim et al. 2014; Zorba et al. 2011; Shreedhar et al. 2018; Corbillon et al. 2016). Figure 2 presents a basic framework of collaborative multipath transmission which involves the two types of collaborative multipath transmission technologies.

Internode collaborative multipath transmission: In this situation all the network nodes within the connection session can participate in the operations of the multipath transmission. Taking the data sender and the receiver, for example, both of the two nodes can work collaboratively with each other to efficiently perform all important tasks such as path estimation and selection, flow/congestion control, and energy saving, which means, the receiver not only participates in and contributes to multipath transmission by giving feedback information to the corresponding sender in the form of acknowledgments but also acts as a decision-maker to make meaningful decision according to its obtained firsthand knowledge.

Figure 3 presents a typical scenario of internode collaborative multipath transmission between the sender and receiver sides. This collaborative

Collaborative Multipath Transmission, Fig. 2 A basic framework of collaborative multipath transmission

transmission mode has a potential for achieving many and attractive benefits (in comparison with the traditional sender-centric multipath transmission mode):

- Load balancing (Quan et al. 2017). In the traditional sender-centric mode, a sender needs to perform all important tasks and can become “bottleneck” in multipath transmission. Mov-

Collaborative Multipath Transmission, Fig. 3 Internode collaborative multipath transmission: A basic scenario

ing some tasks from the sender side onto the receiver side to make collaborative work can balance overhead and share load between the sender and receiver.

- Computing power aggregation. The collaborative multipath transmission mode not only can eliminate the performance bottleneck caused by the single sender node but also can aggregate the computing power of both the sender and receiver for effective multipath transmission.
- Proper decision-making. In practice, the receiver knows better than the sender about the characteristics of the last hop of the connection path. Thus, the receiver can perform a proper decision-making in some operations such as path quality estimation, by collaborative communicating with the sender.

Intra-node collaborative multipath transmission: As mentioned earlier, intra-node collaboration refers to cross-layer collaborative communication among each layer of the protocol stack. The benefits of applying the cross-layer collaborative transmission solution to wireless networking have been demonstrated to be very useful for achieving better performance or a global optimization of the wireless network. Compared to the traditional layered multipath transmission mode, an intra-node collaborative multipath transmission mode

mainly has the characteristic of some following aspects:

- Message communication among various network protocol stacks does not follow strict layering principles, which means information from any one of layers in the protocol stack is contributed and made available to another layer(s).
- An efficient cross-layer adapter or engine has to be included in the networking protocol architectures to violate the conventional strict layering principles and support cross-layer collaborative communication.

We here take, for example, the transport layer-based multipath transmission protocols. Figure 4 illustrates a basic scenario of applying intra-node (cross-layer) collaboration approach to the transport layer. As the figure shows, there is a cross-layer collaboration engine that is embedded into the transport layer protocols for handling cross-layer information. By using the cross-layer collaboration engine, the transport layer can exchange information to the rest layers of the protocol stack or vice versa in order to make a proper transmission behavior or/and decision-making. For instance, the transport layer may exchange information to the application, network, data link, and physical layers in order to obtain the real-time quality-of-service parameters, routing metrics, frame error rate, and channel information,

Collaborative Multipath Transmission, Fig. 4

Intra-node (cross-layer) collaborative multipath transmission: a basic scenario

respectively, to improve the overall transmission performance.

Future Directions

The recent emergence of collaborative multipath transmission technologies has great potentials for enabling a multi-homed network device to concurrent use of multiple network links toward collaborative multipath. However, there are still several design requirements and challenges to be addressed:

- In practice, different nodes with different characteristics (i.e., computing capacity, energy power, and work load) are more commonplace. These differences among the nodes can cause performance degradations of collaborative multipath transmission. How to select a subset of suitable nodes for collaborative multipath transmission is an interesting challenge worth further investigation.
- Another concern when applying collaborative multipath transmission technologies or, more accurately, the internode collaborative multipath transmission technologies to traffic data delivery is related to the system time synchronization problem. How to make the clocks of all the nodes to be synchronized perfectly is still a hard problem.

Collusion

Fan Wu and Dan Peng
Department of Computer Science and Engineering, Shanghai Jiao Tong University, Shanghai, China

Synonyms

[Bid rigging](#); [Cartel](#); [Collaborative cheating](#); [Price agreement](#); [Tacit collusion](#)

Definitions

In markets where game theory and mechanism design are used for resource allocation or cost sharing, agents are independent and rational, i.e., each agent aims to get higher individual utility for itself. Collusion takes place when a subset of agents deviates from the strategy of truthfully reporting their private information to manipulate the game outcomes.

Historical Background

Collusion is a pervasive problem in markets. Agents have the incentive to collude and cheat, when collusion is profitable, e.g., they can gain more group utility as well as individual utilities.

Many case studies in practice show that traditional auctions are vulnerable to collusive behaviors. For example, in previous FCC spectrum auctions (Cramton and Schwartz 2000), where the bids for spectrum licenses were large in hundreds of millions and there were no constraints on the submitted bids, bidders signaled with the last three digits of their bids and coordinated a collusive agreement on the spectrum licenses. The design of simultaneous open bidding and full information revelation makes ascending auctions vulnerable to bidder collusion.

There are also a number of research studies on collusion analysis. To facilitate peer contribution (e.g., disseminating and sharing files) and

to avoid free-riding (i.e., downloading files without uploading any in return), P2P file-sharing systems always incorporate incentive mechanisms based on virtual currency or reputation. However, measurements in Yang et al. (2005) reveal that pair-wise colluding groups exchanged data aggressively to earn uploading points. Yet, another example is in secondary spectrum markets, where second-price auctions are designed for on-demand short-term spectrum redistribution in wireless networks. While truthful auctions function well in discouraging bidders from individual cheating, they become ineffective in the case of bidder collusion. Experiments in Zhou and Zheng (2010) show that colluding groups even in small size and simple pattern can easily increase group utility and degrade auction revenue.

In wireless ad hoc networks (WANETs), source node depends on other intermediate nodes to forward data to destination node. Therefore, cooperation of wireless nodes (which belong to individual agents and perform in their own interests) is crucial for the networks to function effectively. Over the last few decades, research effort on mechanism design in this field mainly focuses on two parts: routing decision-making (Wang and Li 2006; Zhong and Wu 2010) and packet forwarding (Li and Wu 2010; Chen et al. 2011). Although truthful mechanisms guarantee that no individual agent can benefit from unilateral deviation, they are still susceptible to agent collusion. For example, if two nodes realize that they are critical nodes (i.e., their failure will divide the network to disconnected parts), they can collude to declare arbitrarily large routing costs and charge a monopoly price together.

Collusion-Resistant Mechanisms

While the colluding agents benefit from cheating, the overall system performance (e.g., efficiency, fairness, and revenue) may degrade seriously. Therefore, it is significantly important for systems to design collusion-resistant mechanisms, either making collusion difficult to form or leaving agents no incentive to collaboratively cheat.

FCC Spectrum Auction

Collusion can be mitigated by appropriately enhancing the particular rules of the auctions. In the FCC spectrum auction, the revealed information about bidding and bidder identity can affect its susceptibility to bidder collusion (Cramton and Schwartz 2000; Marshall and Marx 2009). First, by specializing the three trailing digits of its bid, a bidder in the FCC auction could tell the others its demand for some certain license and warn its rivals that they would better withdraw their bids to avoid punishment. So, cutting the trailing digits of bids, setting standardized bid increments, and limiting the number of withdraws will increase the signaling cost and thus alleviate collusion. Second, revealing bidder identities allows retaliatory bids (i.e., punishments for breaking the collusive agreement) and utility transfer (i.e., payments from the winning cartel to its cartel members). Withholding the identity information of bidders can make collusion more difficult.

Compared to the open ascending auctions, second-price auctions, where bidders submit sealed bids and the highest bidder wins and pays the second highest bid, are supposed to be more robust to collusion, since they formally avoid bid signaling and bidder identity revelation. However, most truthful mechanisms, including the celebrated Vickrey-Clarke-Groves (VCG) mechanism (Vickrey 1961; Clarke 1971; Groves 1973), are vulnerable to bidder collusion. Robinson (1984) presented the theoretical evidence.

Wireless Spectrum Allocation

To characterize the property of collusion-resistance, Goldberg and Hartline (2005) proposed a strong notion of truthfulness. A mechanism is t -truthful if no collusion group of size t or less can improve its group utility even when colluding agents can transfer utilities within the group. In this context, the only t -truthful mechanism for single-item multiunit auctions is the trivial posted price scheme. While posted price may lead to large revenue loss, mechanisms, which are t -truthful with high probability but can approximately achieve either

revenue maximization or efficiency, are more desirable.

Zhou and Zheng (2010) proposed a (t, p) -truthful mechanism to address bidder collusion in large-scale spectrum auctions. In the original pricing mechanism (Zhou et al. 2008), a winner is charged by the bid of its critical neighbor, also known as critical value (i.e., the bidder wins if bidding higher than this value and loses if bidding lower). A representative collusion pattern is Winner Critical Neighbor collusion. Winner W bids a high price to compete for the spectrum, and the critical neighbor C bids an amount, which is lower than its true value but maintains her critical position. If W wins and pays C 's bidding price, then W and C successfully gain more group utility by collusion. To mitigate collusion, the proposed mechanism divides bidders with interference into different groups, selects a price and potential winners for each group, and then selects winning groups based on their group revenue. By randomizing the winner selection and rounding the group revenue, this (t, p) -truthful mechanism makes the allocation result insensitive to bid changes and thus guarantees with a probability of at least p that no collusion group of size t or less can gain a higher group utility by bid rigging.

Yet, another work Ji and Liu (2008) proposes a multistage pricing game to address bidding rigging collusion in dynamic spectrum auctions. Buyers collude and suppress competition through bid rigging. When they get higher utilities, the allocation efficiency and seller's utility diminish. To alleviate this problem, the seller sets an optimal reverse price. Wu et al. (2009) studied loser collusion and sublease collusion. In the former case, bidders collude to raise their bids to compete for spectrum; in the latter case, bidders who win in the auction sublease their spectrum to losers to earn extra utilities. Both types of collusion will affect the efficiency, fairness, and revenue. To combat collusion, the multi-winner auction due to spectrum reusability is remodeled as a single-winner second-price auction. Bidders with negligible interference are grouped together

as virtual bidders and assigned the sum of their individual bids as virtual bids. The virtual bidder with the highest virtual bid would win the spectrum, and each bidder in this virtual group has to pay an equilibrium price. High prices make losers unlikely to aggressively raise their bids, and strict constraints on the prices leave the winners little incentive to release their spectrum. Both of the two mechanisms are immune to one or more patterns of bidder collusion.

Routing in Wireless Ad Hoc Networks

A mechanism is *group strategyproof* if no group deviation can strictly improve the utility of a single agent in the group without strictly harming another one (Jain and Mahdian 2007). In this definition, an important assumption is that the utility is not transferable. That is, an agent that benefits from collusion will not compensate another agent that suffers a loss, which is different from that of t -truthful mechanism and (t, p) -truthful mechanism.

In wireless ad hoc networks, wireless nodes rely on other intermediate nodes to forward packets. Before the forwarding is possible, source nodes have to make routing decisions about which path they prefer to take. To make routing decisions, a node needs to know the information of relaying costs of other nodes in the network. Being rational, the wireless nodes strategically maximize their own utilities and collude to gain group utility if possible. In theory, group strategyproof mechanisms are more powerful than strategyproof mechanisms in sustaining the network stability.

However, group strategyproofness cannot be achieved when utilities gained by collusion is transferrable among colluding agents (Wang and Li 2006). In other words, it is impossible to design a t -truthful pricing mechanism for the least-cost unicast routing problem in WANETs even for $t = 2$. In Zhong and Wu (2010), the assumption of transferable utility is relaxed but prevented via cryptographical techniques. When agents do not fully trust each other and cannot

convince the others of their actions, they are unlikely to transfer utilities. Even without the assumption of transferable utility, there is still no group strategyproof equilibrium.

Nevertheless, a positive result is that there exists a strong Nash equilibrium after cost discretization, and it achieves social efficiency (Zhong and Wu 2010). A *strong Nash equilibrium* is a Nash equilibrium where no group can benefit all of its members by deviation, taking the actions of its complements as given. In this context, when others tell the truth, the optimal strategy for the group is to tell the truth as well.

Packet Forwarding in Vehicular Ad Hoc Networks

While noncooperative game theory studies strategy and payoff of each individual agent, cooperative game theory considers how to enforce and sustain cooperation among agents. Typical scenarios include (but are not limited to) value allocation and cost sharing.

In cooperative games, group strategyproofness is also called coalitional rationality. In the VANET coalitional game (Chen et al. 2011), a collusion-resistant coalition that enforces all vehicles to cooperate and forward packets via opportunistic connections was proposed. In general, a coalition is a subset of vehicles, and it can obtain a value or payoff if the vehicles in the coalition cooperate with each other. By carefully designing the payoff allocation mechanism, the VANET coalitional game achieves a stable grand coalition. The grand coalition can maintain cooperation among all vehicles and thus is robust to packet forwarding collusion. Even though the payoff allocation depends on the forwarding records submitted by the individual vehicles, the mechanism avoids record cheating collusion by checking and verifying the forwarding records. Therefore, the payoff allocation mechanism achieves coalitional rationality or group strategyproofness.

Open Questions

A general question is, what other applications and scenarios in wireless networks are vulnerable to collusion? Both Nash equilibrium and dominant-strategy equilibrium are susceptible to collusion (Feigenbaum et al. 2007). Being observable or hidden, collusion is hard to detect, even in small size and simple pattern. Although several case studies have dug collusion patterns, there is still no formal definition for collusion or complete characterization of collusion patterns.

In addition, many questions about the collusion-resistant mechanisms have not been fully answered. Collusion-resistant mechanisms make collusion less attractive. However, given different objective functions and constraints, little is known about the existence of collusion-resistant mechanisms, and the necessary and sufficient conditions have not been comprehensively understood.

Definition

Tiny volumes of fluids, so-called droplets, are used for communication and/or networking purposes in microfluidic chips.

Historical Background

Communications in microfluidic channels is a type of molecular communication. In Bicen and Akyildiz (2014), the transport of molecules that are dispersed into a continuous fluid in a microfluidic channel has been investigated. In droplet-based microfluidics, droplets flow in microfluidic channels inside an immiscible continuous flow. The droplets can be independently controlled and manipulated, paving the way for communications, computing, and networking in microfluidic chips.

Droplet-Based Communications

The idea of encoding/decoding of information using droplets has been, for the first time, introduced in Fuerstman et al. (2007). In particular, the distance between two droplets has been used for information encoding, and experimental results have been presented. Later on, various other encoding schemes have been defined in De Leo et al. (2012, 2013), including

presence/absence of droplets, size of droplets, and substances composing the droplets. Channel capacity expressions for presence/absence, size, and type encoding have been presented in De Leo et al. (2012, 2013), assuming no droplet coalescence. However, no closed-form expressions can be found if the aforementioned assumption is not satisfied, and, thus, a numerical analysis of the channel capacity has been presented in Galluccio et al. (2018). For information encoding using the inter-droplet distance, a closed-form expression for the channel capacity is given in De Leo et al. (2012, 2013). The error performance when information is encoded in the droplet size and the inter-droplet distance has been evaluated experimentally in Biral et al. (2015b). Moreover, the tradeoff between data rate and error probability for substance-based encoding has been investigated in Galluccio et al. (2015).

Droplet-Based Networking

The principle of controlling the droplets' path in a network of microchannels by only exploiting hydrodynamic effects has been, for the first time, introduced in Prakash and Gershenfeld (2007). In this work, this principle has been used for the implementation of logic gates. The interconnection of microfluidic devices (e.g., lab-on-a-chip (LoC)) in a microfluidic network has been proposed in De Leo et al. (2012, 2013), with the aim of realizing programmable, flexible, and biocompatible microfluidic chips. The microfluidic devices are interconnected using so-called microfluidic switches, which control the droplets' path within the network by only exploiting hydrodynamic effects. Two different types of switches have been proposed so far, namely, single-droplet switch in Cristobal et al. (2006); De Leo et al. (2013) and multiple-droplet switch in Castorina et al. (2017). The former switch controls the path of a single droplet, while the latter controls multiple droplets. The single-droplet switch has been deployed in different network architectures, using different addressing schemes to steer the droplet to the targeted microfluidic device. For example, a ring network where the distance between droplets is exploited for addressing purpose has

been reported in De Leo et al. (2012, 2013). Moreover, a bus network where the addressing is based on the droplet size and the inter-droplet distance has been introduced in Zanella and Biral (2014) and in Donvito et al. (2016), respectively. A comparison between both addressing methods has been presented in Hamidović et al. (2018).

The multiple-droplet switch can only be used in bus networks, which has been investigated in Castorina et al. (2017). In order to avoid droplet collisions in microfluidic networks, a device for medium access control has been proposed in Donvito et al. (2013). Before fabrication, the microfluidic networks are usually simulated. Unfortunately, conventional computational fluid dynamics (CFD) simulations are very time-consuming and require high computational costs. Thus, two tools especially dedicated to the simulation of microfluidic networks have been reported in Grimmer et al. (2018a) and Biral et al. (2015a), where both methods are based on the analogy between microfluidic networks and electrical circuits.

Foundations

Droplet-Based Communications

The encoding of information using droplets can be done in many different ways. In the following, a brief description of different encoding schemes is given, and the corresponding capacity/throughput formulas are presented.

Presence/Absence of Droplets: In this case, the transmission is divided into time slots, each of duration T_b . Within this time slot, a droplet is generated for bit 1, and no droplet is generated for bit 0 (see Fig. 1a). Assuming that droplets do not leave their slot, the throughput for this encoding scheme is given in De Leo et al. (2012) as

$$C_{\text{DPA}} = \frac{1}{T_b}. \quad (1)$$

Size of Droplets: In this case, different droplet sizes are generated to convey information. Several droplet sizes can be used to encode symbols that represent several bits. For example, four

Communications and Networking in Droplet-Based Microfluidic Systems,

Fig. 1 Different droplet-based information encoding schemes for communications in microfluidic chips: (a) Presence/absence encoding; (b) size encoding; (c) composition encoding; (d) distance encoding

different droplet sizes are required to encode symbols that represent two bits (see Fig. 1b). Thus, assuming that the droplets do not leave their time slots, the throughput is given by

$$C_{DS} = \frac{m}{T_s}, \quad (2)$$

where T_s and m denote the duration of a symbol time slot and the number of bits per symbol, respectively. This encoding scheme is a generalization of the presence/absence encoding scheme.

Composition of Droplets: In this case, the information can be either encoded in different substances composing the droplet or in different molecules encapsulated inside the droplet (see Fig. 1c). Similar to size-based encoding, various substances/molecules can be used to encode symbols that represent several bits. For the binary and non-binary case, the throughput is given by (1) and (2), respectively.

It is important to note that without the assumption that droplets remain in their time slot, no closed-form expression for the capacity is available. This is because then the channel has both memory and anticipation, i.e., the output of the channel in a certain time slot depends on the droplets generated at the previous, the current, and the next slot. In Galluccio et al. (2018), an extensive analysis of this channel based on Markov chains has been presented, and the channel capacity has been evaluated numerically.

Distance Between Droplets: In this case, the information is encoded in the distance between

consecutive droplets. Several distances can be used to encode symbols that represent multiple bits. For example, to encode symbols that represent two bits, four different distances, ΔT_j , $j = 1, 2, 3, 4$, are required (see Fig. 1d). It has been shown in De Leo et al. (2013) that the channel capacity can be written as

$$C_{DD} = \frac{1}{\sqrt{2\pi e \sigma_E^2} \log 2} \exp \left(-W \left(T_{\min} / \sqrt{2\pi e \sigma_E^2} \right) \right), \quad (3)$$

where $T_{\min}$ denotes the minimum time interval between two consecutive droplets to avoid droplet coalescence, e corresponds to the Euler's number, and σ_E^2 is the variance of the random variable representing the difference between the distance at the transmitter and the one at the receiver. Moreover, $W(\cdot)$ denotes the Lambert W function, which is defined by the equation $z = W(z) \exp(W(z))$.

Droplet-Based Networking

The key building blocks of droplet-based microfluidic networks are microfluidic switches. These switches control the droplet's path within a microfluidic network only exploiting hydrodynamic effects. Hence, the main design parameters are the channel geometries and hydrodynamic forces (e.g., volumetric flow rate). In the following, first, two different types of microfluidic switches are introduced, and then

their application in microfluidic bus networks is shown.

Microfluidic Switches: Microfluidic switches control the path of so-called *payload* droplets using so-called *header* droplets. Payload droplets contain chemical or biological samples that are sent to a certain network node (microfluidic device) for processing. On the other hand, header droplets contain no samples and are only used for signaling purpose. Two different types of switches have been proposed so far: single- and multiple-droplet switches, controlling the path of a single and multiple droplets, respectively.

The single-droplet switch is shown in Fig. 2 and consists of a T-junction, two asymmetric channels 1 and 2, and a bypass channel. The lengths of channels 1 and 2 are given by L_1 and L_2 , respectively. Due to the bypass channel, the switch only depends on the geometry of channels 1 and 2, which is an important property when multiple switches are cascaded in a network. It is assumed that channel 1 is longer than channel 2, i.e., the hydrodynamic resistance of channel 1 is higher than that of channel 2. If a payload droplet with a leading header droplet flows toward the T-junction, the header droplet flows into channel 2, due to its lower hydrodynamic resistance. If the following payload droplet arrives at the T-junction before the header droplet has left channel 2, it flows into channel 1 (see Fig. 2a). This is because the header droplet increased the hydrodynamic resistance of channel 2 such that it is higher than in channel 1. If the header droplet has already left channel 2, the payload droplet follows the header droplet into channel 2 (see Fig. 2b). Thus, whether the payload droplet takes channel 1 or 2 is encoded in the distance to the preceding header droplet.

The multiple-droplet switch is shown in Fig. 3 and consists of a control and a switching region. The switching region contains an asymmetric junction with channels 3 and 4, where channel 3 (length L_3) is longer than channel 4 (length L_4), i.e., channel 3 has a higher hydrodynamic resistance than channel 4. The basic idea of this switch is that a droplet in the control region controls the path of a droplet which is currently in the switching region. In particular, a droplet at the

Communications and Networking in Droplet-Based Microfluidic Systems, Fig. 2 Single-droplet switch (header and payload droplets are labeled by “H” and “P”, respectively): (a) the distance between payload and header droplet before the junction is smaller than L_2 , and, thus, the droplets flow into different channels; (b) the distance between payload and header before the junction is greater than L_2 , and, thus, both droplets flow into the same channel

switching region flows into channel 4, if the following droplet clogs the control channel in the control region (see Fig. 3a). This is because the hydrodynamic resistance of channel 4 is lower than that of channel 3. On the other hand, a droplet arriving at the switching region flows into channel 3, if the control channel is not clogged by the following droplet (see Fig. 3b). This is because the flow through the control channel prevents the droplet in the switching region to flow into channel 4. Thus, similar to the single-droplet switch, the distance between the droplets determines the droplets’ path in the multiple-

droplet switch. It is important to note that this switch can be used to control the path of a single or multiple payload droplets only using a single header droplet at the end.

Microfluidic Bus Network: Three different network topologies have been identified for microfluidic networks: bus, ring, and application-specific. In the following, a detailed discussion

Communications and Networking in Droplet-Based Microfluidic Systems, Fig. 3 Multiple-droplet switch (header and payload droplets are labeled “H” and “P”, respectively): (a) the control channel is clogged, and, thus, the payload droplet flows into channel 4; (b) the control channel is not clogged, and, thus, the payload droplet flows into channel 3

on the bus network is provided since it offers the highest flexibility and scalability compared to ring networks and application-specific architectures presented in De Leo et al. (2012) and Grimmer et al. (2018b), respectively. Moreover, only the bus network allows to apply single- and multiple-droplet switches. The topology of a microfluidic bus network is shown in Fig. 4. Considering the single-droplet switch described above, channel 1 is connected with the network node, and channel 2 is connected with the next switch in the network. The payload droplet can be routed to the targeted network node by generating a header droplet in front. The distance between both droplets determines the targeted node. In particular, if the distance between the droplets is larger than the length of channel 2, both droplets flow toward the next switch, and their distance is reduced. If their distance is below the length of channel 2, the payload droplet is routed to the desired network node for further processing, and the header droplet passes the remaining switches and flows into a sink. Considering the multiple-droplet switch described above, channel 4 is connected with the network node, and channel 3 is connected with the next switch in the network. This switch enables to route multiple payload droplets to the targeted network node with only a single header droplet at the end. This is accomplished through an equally spaced payload droplet train with a header droplet at the end. In particular, the distance between the droplets must be set, such that at the desired network node, the previous droplets clog the control channel and, thus, the droplet at the switching region flows toward the targeted node, i.e., into channel 4. It

Communications and Networking in Droplet-Based Microfluidic Systems, Fig. 4 Microfluidic bus network, where the payload droplet is routed to node 2 for further processing and the header droplet flows toward the sink

is important to note that the last payload droplet is routed by the header droplet at the end. If the control channel is not clogged by the previous droplet, the droplet train passes the switch, and the spacing between the droplets is reduced.

Key Applications

Microfluidic networking is a promising approach for applications which require a fast analysis of biochemical samples and where the viability of the sample must not be compromised. The first requirement can be achieved through parallel processing in a bus network, and the second constraint is implicitly fulfilled since the droplets' path is controlled only exploiting hydrodynamic effects. Recently, two such applications have been suggested, namely, fast and flexible drug screening in Haselmayr et al. (2018) and fast waterborne pathogen screening in Hamidović et al. (2019). The former application enables fast and flexible screening of different types/concentrations of antibiotics on infected human cells (e.g., lung cells), and the latter application proposes a fast analysis of the interaction between water pathogens and different disinfectants.

Future Directions

The research on droplet-based communications and networking in microfluidic chips is still in its infancy. In the past years, a lot of theoretical work has been devoted to this area. However, although many theoretical concepts have been introduced, an experimental validation for most concepts is still missing. An important step toward the practical realization are so-called droplet-on-demand (DoD) systems. Such systems allow the generation of droplets at prescribed times with a certain size and at a certain distance. A promising DoD system has been recently proposed in Hamidović et al. (2019), but a full characterization of this method is still missing.

The identification and practical realization of biological/chemical applications for microfluidic networks is a very important future direction. Such investigations must also include a comparison with well-established methods. In this regard, the practical realization of the applications proposed in Haselmayr et al. (2018) and Hamidović et al. (2019) would be an important step.

Recently, a promising simulation tool for microfluidic networks, based on the analogy between microfluidic networks and electrical circuits, has been presented in Grimmer et al. (2018a). It allows for fast simulation with low computational costs. However, currently only a limited number of components (e.g., droplet trapping) are supported, and, thus, the further development of this simulator is an important future direction.

Another interesting future direction would be the investigation of different network topologies (e.g., microfluidic tree network) and the development of more sophisticated scheduling algorithms. Moreover, the characterization of the network nodes (e.g., mixing) is a crucial step to enable a complete design and analysis of microfluidic networks.

Definition

Mobile edge computing (MEC) is an emerging paradigm which pursues to provide better services by moving infrastructure-based cloud resources (e.g., computation, storage, bandwidth, and so on) to the edges of mobile networks. MEC is rapidly becoming a key technology of the fifth-generation (5G) mobile networks, which helps to achieve the key technical indicators of 5G business, such as ultra-low latency, ultra-high energy efficiency, and ultra-high reliability.

Computation offloading refers to that mobile users (MUs) send heavy computation tasks to edge servers (ESs) and receive the processed results from them. The goal of computation offloading is to minimize the total energy consumption or overall task execution time or both of them.

Historical Background

With the rapid development of mobile communications and the explosive usage of mobile devices carried by MUs, mobile Internet facilitates us with a pervasive and powerful platform to provide increasingly emerging applications. However, mobile devices generally have limited computation capabilities and battery power. Migrating computational applications from geographically distributed mobile devices to the infrastructure-based cloud servers has the potential to address the above issues. The remote cloud is always located in the center of core network and far away from MUs, which may cause delay fluctuation and additional transmission energy cost. In order to deal with the issue of network delay, MEC has been proposed as a new and effective paradigm (Shi et al. 2016; Wang et al. 2018a).

As illustrated in Fig. 1, the MEC architecture can be seen as a middle layer between MUs and the remote cloud which is closer to MUs and provide services for them. In addition, it can also be seen as an independent two-tier architecture consisting of MUs and ESs. Mobile devices carried

by MUs generally refer to smartphones, tablets, laptops, and so on. In addition, ESs generally refer to base stations combined with servers or cloudlets. MUs offload computing applications to ESs, which not only enables MUs to execute applications efficiently but also reduces latency caused by accessing the remote cloud. Computation offloading was originally investigated in mobile cloud computing (MCC). Computation offloading in MEC is similar to MCC, but the main difference is the offloading destination (Peng et al. 2018). It is generally assumed that the implementation of MCC computation offloading depends on a network architecture with the remote cloud, while the destination of computation offloading in MEC is ESs, such as cloudlets or base stations.

Foundations

From the perspective of task division, computation offloading can be further divided into full computation offloading and partial computation offloading. From the perspective of offloading destinations (i.e., cloudlets or base stations), computation offloading can be divided into computation offloading in cloudlet-based MEC and computation offloading in base station-based MEC. More details are shown as follows.

Full Computation Offloading

Full Computation Offloading in Cloudlet-Based MEC

Full computation offloading in cloudlet-based MEC mainly focuses on the cloudlet selection among multiple cloudlets. The goal of cloudlet selection is to choose the cloudlet that meets a MU's minimum latency, or the MU's least energy consumption, or the minimum of both goals. A proxy server can be used for cloudlet selection (Mukherjee et al. 2019); however, the latency between MUs and the proxy server also needs to be considered.

If cloudlets have the same capabilities and provide the same type of services, the cloudlet selection problem may become relatively simple.

Computation Offloading in Mobile Edge Computing, Fig. 1 Mobile edge computing architecture

Namely, the nearest cloudlet is the best choice. Actually, these cloudlets are heterogeneous and have different computing capacity constraints (Xu et al. 2016), and thus it is critical to develop application-aware selection algorithm (Roy et al. 2017). More specifically, cloudlets are resource-constrained, and thus cloudlet selection and resource allocation should be taken into account jointly (Liu and Fan 2018; Zhang et al. 2018a).

VM-based cloudlet architecture is presented (Satyanarayanan et al. 2009), and a new cloudlet architecture in which applications are managed at the component level is proposed (Verbelen et al. 2012).

In addition, when the problem is switched from single-MU scenario to multi-MU scenario, the problem becomes more complicated. It is necessary to consider using game theory or deep supervised learning method to solve the problem (Yu et al. 2017; Cao and Cai 2018).

Full Computation Offloading in Base Station-Based MEC

Single-MU full computation offloading and multi-MU full computation offloading are two important issues, which need to be addressed. Different from the former mode, allocation of different types of resources, including access point association, interference management, physical resource block allocation, as well as radio resource allocation, needs to be considered in base station-based MEC.

Power consumption and the execution latency are two key goals in MEC systems (Mao et al. 2016). Moreover, minimizing the total energy consumption of access points under the MUs' individual computation latency constraints is also critical (Ketykó et al. 2016). In addition, when multiple MUs attempt to transmit data simultaneously on a shared network, the transmission collisions may occur, which is also need to be concerned (Tran and Pompili 2018).

Overall, game theory and Lyapunov optimization method as well as queuing theory can be used to figure out the above issue.

Partial Computation Offloading

Partial Computation Offloading in Cloudlet-Based MEC

Some applications, such as workflow tasks (Xu et al. 2018), can be further divided and distributed to multiple cloudlets to improve execution efficiency. In particular, some tasks can only be performed locally. Partial computation offloading can make the parallelism between mobile devices and cloudlets maximized (Jia et al. 2014).

Graph theory and 0–1 integer programming methods can be used to solve the above problem (Wu et al. 2016). Moreover, it should be noted that cloudlets are resource-constrained. In other words, tasks need to be migrated to the remote cloud or migrated back to the local execution while meeting the tasks' deadline when cloudlets cannot provide required services.

Partial Computation Offloading in Base Station-Based MEC

MUs divide tasks into sub-tasks and offload them to multiple base stations. Minimum latency and minimum energy consumption are two basic optimization goals. Meanwhile, the reliability in partial computation offloading needs to be studied (Liu and Zhang 2018). Multiple sub-parts of multiple tasks make the queue delay problem more complicated. Dynamic voltage scaling technology can be used for partial computation in base station-based MEC (Wang et al. 2016).

Key Applications

The technique of computation offloading in mobile edge computing can be utilized for improving quality of service (QoS) of MUs, such as in cloud gaming, OCR (Li et al. 2018), augmented reality (Jia and Liang 2018), and smart home (Zhang et al. 2018b), and also for

deploying future network architecture such as large-scale networks Internet of Vehicle (IoV) systems (Wang et al. 2018b).

Future Directions

From the evolution of computation in mobile edge, it appears that, in the future, emphasis will be given on the following research directions as follows:

- Deep learning-based computation optimization
- Joint computation offloading and resource allocation
- Cross layer resource optimization
- Multi-cloudlet resource optimization

Connectedness of Molecular Nanonetworks

Definitions

Connectivity refers to a global structural network property that enables exchange of information between every pair of nodes in the network. In a nanonetwork, the nodes or nanomachines making up the nanonetwork can employ molecular signaling as a means of communication. In the most general diffusion-based molecular signaling, the transmitter nanomachine releases information-carrying molecules that diffuse in a medium to reach a receiver nanomachine. If molecular signals cannot be detected by a destination nanomachine directly, intermediate nanomachines can relay the information toward the destination also by emitting molecular signals. Therefore, if exchange of information between every pair of nanomachines is possible, either directly or indirectly, through the release and reception of molecules, the molecular nanonetwork is said to be connected.

Historical Background

Recent developments in nanotechnology enable the design and manufacture of nanomachines or devices that are made up of nanoscale components. By themselves, nanomachines can perform only simple computation, sensing, and actuation.

An interconnection of nanomachines is usually formed to enable cooperation and sharing of information to achieve more complex and useful tasks. Such nanonetworks have a wide range of potential applications in biomedicine, industry, environment, and military (Akyildiz et al. 2011).

Two main alternative communication paradigms considered for nanonetworks are nano-electromagnetic communication and molecular communication (Akyildiz et al. 2011). A feasible and biocompatible means of information transport in nanonetworks with no infrastructure can possibly be free diffusion-based molecular signaling. It is conjectured that biologically inspired nanomachines with molecular communication capabilities can be built by genetic modification of existing cells or by manufacturing artificial cells. One can refer to Farsad et al. (2016) for a very extensive survey on recent results and issues on molecular nanonetworks.

Molecular signaling mechanisms can especially be useful for broadcasting an alarm by transmitting a “puff” of molecules that will freely diffuse in a fluidic medium. Such systems can be employed for detection and handling of abnormal events, pathogens, and cancerous cells in some part of the body. Molecular concentration detectors built into nanomachines can decide whether the signal reception is successful or not based on a prespecified detection threshold. Upon detection of the molecular signal, receiver nanomachines can transmit their own molecules into the fluidic medium in a coordinated manner to percolate the alarm throughout the network provided that the network is connected. Hence, the conditions under which connectivity is achieved must be thoroughly investigated for these types of nanonetworks.

Connectivity of ad hoc wireless and sensor networks is a well-investigated subject; for example, see Krishnamachari (2005), Franceschetti and Meester (2008), and Haenggi (2012), and the references therein. However, there is relatively less work on connectivity properties of molecular nanonetworks. A recent study by Arifler (2017)

identifies differences between ad hoc wireless network and molecular nanonetwork connectivity and analyzes the connectivity properties of nanonetworks that employ free diffusion-based molecular communication.

Foundations

A network has the highest utility when any two nodes can communicate with each other. Connectivity is a graph theoretic concept (Rosen 2012). A network can be modeled as an undirected graph where the vertices are the network nodes and there is an edge between a pair of vertices if the corresponding nodes can directly communicate with each other; in other words, the edges have no orientation and correspond to communication links. A path is a sequence of edges that starts at a vertex and follows vertices along these edges of the graph. Two network nodes are connected if there is a path between them. A network is said to be connected if all pairs of nodes in the network are connected. Figure 1 depicts a connected network (Fig. 1a) and a disconnected network (Fig. 1b). Note that having all pairs of nodes connected is a strict requirement, and in practice, an almost-connected network (e.g., having at least 99% of the nodes connected) may be of greater interest.

Ad hoc wireless and sensor networks are generally modeled as two-dimensional planar networks, and the signal strength at a receiver is

inversely proportional to the α th power of the distance from the transmitting source, where α is the path loss exponent and is generally greater than 2. The nodes in large-scale networks are usually scattered randomly into an environment. Hence, a homogeneous Poisson point process can be used to model locations of randomly deployed nodes. With node locations as the vertices and direct links as the edges, the graph so formed is a random geometric graph (Haenggi 2012). In widely studied random graph models of wireless networks, there are critical values for the transmission power and the number of nodes above which the network is connected and below which the network is disconnected with high probability. Such a phenomenon of an abrupt change in the global behavior of a system in response to a small change in one of its parameters is called a phase transition (Franceschetti and Meester 2008). In a nanonetwork, the locations of nanomachines scattered randomly into a medium can also be modeled by a homogeneous Poisson point process. Yet, the nature of signal propagation in free diffusion-based molecular communication is very different: the strength of the signal observed at a receiver nanomachine is inversely proportional to the d th power of the distance from the transmitter, where d is the dimensionality of the medium. Hence, an investigation of the phase transition behavior specific to nanonetworks is necessary. In particular, determination of critical values of important nanonetwork parameters is of great interest since a nanonetwork might

Connectivity via Molecular Signaling, Fig. 1 (a) A connected network where there is a path between any two nodes and (b) a disconnected network

be disconnected and hence be of limited use if under-provisioned, or a nanonetwork might consume more resources than necessary if over-provisioned.

Perfectly monitoring spheres (Endres 2013) can model nanomachines that continuously and passively count molecules within their transparent volumes without disrupting the diffusion process. This type of receiver nanomachines can correspond to chemosensory detection systems in which ligands freely enter and leave the perireceptor space in a fast and reversible manner (Rospars et al. 2000). It may be assumed that nanomachines can instantly count the number of molecules within their volumes to estimate the concentration at their centers, but the molecule count is inherently noisy due to diffusion. Analogous to traditional communication systems, one can define the instantaneous signal-to-noise ratio (SNR) at a receiver nanomachine as the “power” of the molecular signal component divided by the power (variance) of the noise component in the received molecular concentration.

When communicating, each nanomachine can release particles with its self-identifying label that can be distinguished by receivers. Such a medium access mechanism has been termed as molecular division multiple access (MDMA) and was discussed in Giné and Akyildiz (2009) and Kuscu and Akan (2016). In a single “puff,” each nanomachine emits Q particles (also referred to as the signal strength), and it can be assumed that all the nanomachines in the network have the same SNR detection threshold β . It can also be assumed that a previously emitted “puff” from a given nanomachine fades out before another one can be emitted by that nanomachine. Within this framework, the SNR at a receiver centered at $\mathbf{r} \in \mathbb{R}^d$ relative to the transmitter can be determined. With the assumption of self-identifying labels, one can say that nodes that are separated by a distance $\|\mathbf{r}\|$ are directly connected if the maximum SNR detected is greater than β . Monte Carlo simulation results in Arifler (2017) indicate that a phase transition behavior similar to that in ad hoc wireless networks is also observable in

nanonetworks as the parameters signal strength-to-detection threshold ratio Q/β and the number N of randomly deployed nanomachines are varied. For illustrative purposes, Fig. 2 shows connectivity probabilities for three-dimensional nanonetwork scenarios with prespecified parameters. Note that, as shown also in Fig. 2, these results are consistent with the probabilities of having a connected network obtained via analytical models based on the diffusion equation in conjunction with the assumption of a Poisson point process as applied to infinitely large networks. Further details and the results for one- and two-dimensional nanonetworks can be found in Arifler (2017).

The time required to broadcast an alarm in a network is another important performance indicator. A simulation-based analysis can again be used to quantify this indicator for molecular nanonetworks with perfectly monitoring receivers. In a recently investigated scenario (Arifler 2017), the originator of the alarm is located at the geometric center of a given region, and the rest of the nanomachines are deployed completely randomly. The time scale at which consecutive alarm pulses are transmitted by the originator can be assumed to be much larger than the time required for the pulses to fade out in the medium. The nanomachines transmit their own signals (only once) as soon as the SNR detected exceeds a prespecified threshold. In this particular scenario, all the nanomachines are assumed to transmit the same type of molecule. At a given time instant, the concentration at a receiver due to activated transmitters is merely a superposition of all their contributions. Hence, multiuser interference occurs, but this interference is *constructive*; emissions from multiple nanomachines enhance the signal at a receiver and help detect the alarm at an earlier time. The results show that the broadcast time decreases with increasing number of nanomachines in the network. Power-law relationships between the time to broadcast an alarm and the number of nanomachines deployed can be postulated for fixed regions with different dimensionalities. In addition, for a given total molecule budget, having a

Connectivity via Molecular Signaling, Fig. 2 Probability of having an almost-connected network as a function of (a) signal strength-to-detection threshold ratio Q/β with $N = 1000$ nanomachines and (b) M ($N = M^3$) with $Q/\beta = 7 \times 10^6$ in a three-dimensional ($1 \text{ mm} \times 1 \text{ mm} \times 1 \text{ mm}$) region where the diffusion coefficient is $10^{-9} \text{ m}^2/\text{s}$ and spherical receiver nanomachines have a radius of $1 \mu\text{m}$. Note that the

Monte Carlo simulation results shown are based on 50 independent runs, each with a different realization of nanomachine positions; the probabilities of an almost-connected network are estimated as the fraction of realizations with at least 99% of the nodes connected. The probabilities of having a connected network obtained via analytical models are also included for comparison. (Adapted from Arifler 2017)

network is extremely beneficial for speeding up diffusion-based propagation of information over a deployment region.

Key Points

The dependence of network connectivity on signal strength and detection threshold has different functional forms for ad hoc wireless networks and molecular nanonetworks. Large-scale two- and three-dimensional networks modeled as random geometric graphs are connected with high probability when the probability of having an isolated node goes to zero (Penrose 1999). With an efficient medium access mechanism in effect, the exponential decay rate of the probability of having an isolated node as a function of signal strength-to-detection threshold ratio is sublinear for ad hoc wireless networks but is linear for molecular nanonetworks (Arifler 2017). This suggests that connectivity can be achieved relatively *more easily* in nanonetworks with increasing signal strength-to-detection threshold ratio.

In ad hoc wireless networks, multiuser interference is detrimental for communication, and interference mitigation techniques are often necessary. In molecular nanonetworks, multiuser interference may prove to be *beneficial* for particular application scenarios that are considered for nanonetworks, such as for propagating an alarm signal throughout the network. Indeed, the empirical studies outlined here show that interference *improves* connectivity in these types of nanonetworks. One may also refer to Deng et al. (2017) for a stochastic geometry-based analysis of superposition of contributions at a single receiver from many molecular transmitters, all of which are transmitting the same signal at the same time.

Due to analytical tractability, Arifler (2017) considers connectivity of nanomachines that perfectly monitor diffusing molecules. An alternative scenario would involve the use of receiver nanomachines that absorb molecules. However, it is conjectured that analytical modeling with many absorbing receivers is nontrivial due to spatial and temporal interdependence among receivers. Monte Carlo simulation schemes

that allow for analysis of molecule absorption probabilities in nanonetworks with multiple absorbing receivers (Arifler and Arifler 2017) can be potentially employed to analyze connectivity in such scenarios.

In summary, due to the inherent phase transition phenomenon in random networks, careful design considerations are required to ensure that a molecular nanonetwork is connected. In particular, it is very important to be able to predict the critical values of signal strength-to-detection threshold ratio and the number of nanomachines to be deployed for which nanonetwork connectivity is achieved. The studies outlined here can thus provide useful design guidelines for nanonetwork deployment.

Contact Plan Design (CPD) refers to select the most appropriate set of feasible communication

This work is supported by the National Natural Science Foundation of China under Grant No. 61572123; the Program for Liaoning Innovative Research Term in University under Grant No. LT2016007.

opportunities in a time-evolving and predictable Delay/Disruption Tolerant Networks (DTN) to deliver data, with fulfilling certain criteria subject to restrictions or limitations.

Historical Background

Traditional geostationary Earth orbit (GEO) satellite relay systems suffer from long round-trip time and frequent channel disruption when they are used for bidirectional and interactive data communication. In deep space systems, longer distance creates higher delay, and planet rotation causes more server disruptions; thus, it is impossible to achieve permanent and conversational communications. Even in low Earth orbit (LEO) satellite systems, disruptions are prevalent, as the high complexity and huge investment are required to maintain end-to-end connectivity. As a result, TCP/IP-based Internet protocols are ineffective against these challenges in GEO, LEO, or deep space systems.

The DTN architecture, which overlays a bundle layer between application layer and transport layer, is recognized as a promising solution for future satellite networks (Caini et al. 2011). It overcomes the delay/disruption problems by using store-carry-forward message scheme. The effectiveness of the DTN paradigm over operational space networks has been tested in real experiments, such as DINET experience and JAXA DRTS testing.

Network topology is a key operational issue in space network design. For different space missions, network topology is controlled under different objectives. Considering the orbital dynamics of space DTN nodes, the contacts (i.e., communication opportunity) among space nodes only can be established when the physical requirements (such as visibility, received power, and antenna pointing) are satisfied. Besides, due to the resource constraints in satellites (such as available transponders and power consumption), not all feasible contacts can be used to route data (Fraire et al. 2013). What's more, different selection criteria (such as capacity and fairness) need to be considered to select the scheduled

contacts for different space applications (Fraire and Finochietto 2015b). This problem is defined as contact plan design (CPD). A short list of representative works on CPD is presented below.

Huang et al. (2010, 2013) proved that the time-evolving graph-based CPD in time-evolving and predictable DTN networks was an NP-hard problem and proposed a greedy-based method which minimized path costs and maximized network connectivity. Based on the min-max fairness, Fraire et al. (2013, 2014) designed a fair-aware CPD strategy that can maximize the global system fairness and the overall capacity simultaneously. However, these two studies assumed that the bandwidth of communication link was constant and the traffic distribution among nodes was uniform.

Wang et al. (2016) considered the time-varying capacities of inter-satellite and satellite-ground contacts to formulate a long-term network throughput maximization problem and derived the optimal contact plan by using efficient heuristic algorithms. Zhou et al. (2017) designed a mission-aware contact plan strategy for small satellite networks, which simultaneously considered mission characteristics, time-varying contact capacity, resource constraints, and basic constraints.

Fraire and Finochietto (2015a) incorporated route information into CPD to design a routing-aware fair contact plan strategy optimizing the fairness and route delays. The traffic of Earth observation mission is predictable, so Fraire et al. (2016) exploited the predictable traffic information to design a traffic-aware contact plan (TACP) strategy, enhancing the schemes proposed in Fraire and Finochietto (2015a).

Contact plans are commonly pre-calculated by the ground control center and delivered to orbiting satellites timely. This implies that valuable and efficient contact plans need to be found out in a reasonable time. To this end, J.A. Fraire et al. proposed a heuristic approach based on evolutionary algorithms to provide sub-optimal yet efficient contact plans in a reasonable time (Fraire et al. 2017, 2015), extending the applicability of TACP to support real and complex satellite DTN missions operation.

Foundations

Terminology

- **Contact:** The contact is a temporal communication opportunity between two DTN nodes. At least a start and stop time and a transmitting and receiving node pair are required to describe a contact. These parameters are determined by orbital dynamics (such as position, range, and attitude) and communication models (such as bit error rate, transmission power, and modulation).
- **Contact topology:** In a given DTN network, the contact topology is formed by all the feasible contacts within a given time interval. In the contact topology, no resource limitation is assumed on nodes, and just the feasibility of physical communication is considered.

- **Contact plan:** Contact plan comprises all forthcoming contacts which satisfy the constraints and special criteria. It is a subset of the contact topology.

Contact Plan Design

In general, the process of CPD can be divided into three stages: topology modeling, problem formulation, and problem-solving. In the initial stage, based on the orbital dynamics and communication subsystem attributes, the feasibility of all communication opportunities is determined to form a contact topology. Then, the contact topology, resource restrictions, and special criteria are taken to formulate the problem model. Finally, algorithm solutions with low computation complexity are designed to solve the problem model to deliver an efficient and implementable contact plan. The process of CPD is illustrated in Fig. 1.

Contact Plan Design for Space Disruption/Delay-Tolerant Networks, Fig. 1
The processing steps of CPD

Contact Plan Design for Space Disruption/Delay-Tolerant Networks, Fig. 2 Topology model of an example satellite networks: (a) five-satellite network, (b) finite

state machine model, (c) contact list model, and (d) space-time model

Contact Topology Modeling Technique

Topology modeling is fundamental to characterize the time-evolving and predictable space DTN networks. A five-satellite network is taken as an example to explain the popular modeling methods, and the corresponding time-evolving topologies are shown in Fig. 2a.

Finite state machine The time-evolving topology shown in Fig. 2a can be characterized by a sequence of graphs, whose vertices and edges, respectively, represent the DTN nodes and feasible contacts among DTN nodes. Specially, the dynamic topology is discretized into K states separated by K time intervals. Each state can be identified by a graph which represents the static topology over a given interval. The feasibility of link between node N_i and N_j at state k can be characterized by a variable $p_{k,i,j}$. As a result, the contact topology can be defined by a three-dimensional adjacency matrix. This representation can be thought as a finite state machine model, as illustrated in Fig. 2b.

Contact list The time-evolving topology can also be characterized by a contact list where each

contact is defined by the starting and end time and the transmitting and receiving nodes. The contact between node N_i and N_j over the time interval $[t_k, t_{k+1}]$ is indicated by $C_{i,j,t_k,t_{k+1}}$. The contact list modeling for the example topology can be represented by four contacts, as illustrated in Fig. 2c.

Space-time graph Alternatively, space-time graph, a directed graph defined in both spatial and temporal space, can be exploited to characterize the evolving topology and network resources. The directed graph is composed of $K + 1$ layers, and each layer corresponds to a network topology at a given time point. The i -th node at time t_k can be denoted by $N_i^{t_k}$. A temporal edge $e_{i,i,t_k,t_{k+1}}$ represents whether node $N_i^{t_k}$ can store and carry data in the k -th time interval $[t_k, t_{k+1}]$. A spatial edge $e_{i,j,t_k,t_{k+1}}$ represents whether node $N_i^{t_k}$ can forward data to node $N_j^{t_{k+1}}$ during the time interval $[t_k, t_{k+1}]$. The space-time graph model of the example topology is illustrated in Fig. 2d.

The contact list model can be expressed by a contact table (Araniti et al. 2015); thus, it is more

compact than finite state machine and space-time graph. However, more detailed and precise topology description can be provided by finite state machine and space-time graph. Thus, finite state machine and space-time graph are convenient for CPD with using MILP optimization. Nonetheless, no matter which modeling technique is taken, the transition among them is straightforward.

Design Constraints and Selection Criteria

Except the contact topology, design constraints and special criteria are generally considered during the CPD problem formulation. The design constraints can be categorized into two groups. One is to determine the feasibility of contacts, named time-zone constraints, such as specific geographical area, time for interference, or other agency-specific reasons. The other one is to limit the contact number that a DTN node can simultaneously support, named concurrent-resources constraints, such as energy consumption, limited storage capacity, available antennas, transponders, etc. Besides these constraints, the selection criteria determined by the particular network purpose are significant to find out the most appropriate contact plan. The selection criteria which have been studied include maximum overall throughput, contact assignment fairness, traffic-driven criterion, mission-driven criterion, etc.

Algorithm Approach

The operating performance of CPD relies on a MILP theoretical model. FCP algorithm based on reduced Blossom algorithm has been designed to determine a fair contact distribution among nodes. To achieve the particular purpose of different networks, heuristics algorithms such as first improvement (FI), steepest descent (SD) and simulated annealing (SA) have been exploited to find the optimum solution from the fair contact plan delivered by FCP. FI and SD just can guarantee to find local optimum solutions; thus, to explore the complete search space, the SA was investigated. Traditional cutting-plane mechanisms were used to solve the TACP model for small space DTN networks, with obtaining an optimal solution in reasonable time. However, the

network scale expansion results in reduced computation complexity and accuracy of these methods. Therefore, approximate methodologies such as population-based meta-heuristics are worth investigating to design CPD strategy with shorter processing time and efficient output.

Key Applications

CPD is involved in efficient data forwarding to support the operations of space DTN networks. It exploits the network predictability to optimize limited resources available and improve network performance. The CPD methodologies introduced above can be used to optimize the network resources in satellite sensor networks, small satellite networks, navigation satellite networks, and Earth observation missions etc. As more information is considered in the planning stage, the rewards of CPD are more effective, while the complexity of CPD process is increasingly large.

Synonyms

Conversational function module for disaster information with speech recognition

Definition

Applies the concepts of conversational chatbots to develop a conversational function module

that supports speech recognition in order to immediately transmit disaster warning information while also allowing users to access disaster-related information through a simple voice response system.

Historical Background

Taiwan is located in an area at high risk of natural disasters. The major natural hazards confronting Taiwan are typhoons and earthquakes. Although natural disasters cannot be avoided, losses can be effectively reduced by improving disaster resilience. As searching for disaster information becomes increasingly complex, when a disaster occurs, the community may find it difficult to immediately digest and understand complex disaster information. In order to allow people to quickly obtain and understand the information they need, easy-to-use disaster warning and information search channels ought to be provided.

With the evolution of technologies such as artificial intelligence and semantic analysis in recent years, many social media companies have developed chatbot services and have provided development modules. This concept uses text or voice conversation to operate functions. This application can analyze user semantics and understand user intentions, thereby providing the information required by the user. Automating the process of information provision can save manpower and time; users only need to be familiar with a single interface and operating procedure in order to obtain the necessary information.

Natural disasters test the resilience of government and the community. Making use of the rapid transmission of information through the Internet together with related technologies can improve disaster resilience and the communication of disaster information. Such technologies can assist us to develop easy-to-use disaster warning and disaster information channels.

On this basis, the Conversational Chatbot for Disaster Information combines the chatbot concept with disaster information, developing a con-

versational function module for disaster information with speech recognition in order to instantaneously transmit disaster warning information; this also allows users to access disaster-related information through a simple voice response system.

Since voice conversation is more natural and intuitive to operate than graphical interfaces, voice operation is increasingly valued by developers (Abdul-Kader and Woods 2015). Using voice control and computer communication, it is possible to reduce manual input time and other necessary steps; in addition, it enables users with disabilities to operate applications using voice functions (Bhargava and Nikhil 2009). For computers to understand human speech, speech recognition technology is required so the computer is able to receive and interpret the words spoken by the user.

After recognizing the natural language spoken by the user, semantic analysis is then used to understand the user's query intention. Semantic analysis needs to first establish a language understanding model, defining a combination of keywords for each possible user query intention. This model analyzes entities and classifies an intention type based on the phrases input by the user. The application can then return the information required by the user based on the results of the analysis.

The Conversational Chatbot for Disaster Information currently provides nine types of real-time data on disaster prevention and data prevention knowledge. Users can query disaster-related information in different regions according to their needs, including rainfall, weather, radar maps, landslide risk areas and warning information, water-level information, warning messages, shelters, as well as typhoon and earthquake information.

Key Applications

Providing the daily weather forecasting and disaster knowledge for public is as the general function of Conversational Chatbot for Disaster Information. When disasters are approaching,

the requests for the real-time observations, disaster alerts, and recommendations can be immediately responded with the contents of graphic information, text, and/or voice.

Microsoft's LUIS cloud semantic analysis service and Microsoft QnA Maker service are used to determine the user's query intent and a disaster knowledge quiz library, respectively. Therefore, according to various query intents, the corresponding real-time data or knowledge-based answers are delivered with messaging API to the user disaster information via graphs, texts, and/or voice.

Definitions

Cognitive radio networks (CRNs) aim to address the issue of spectrum scarcity and meet the ever-increasing spectrum demands. In CRNs, there exist two types of users, i.e., primary users (PUs) and secondary users (SUs), where PUs with licenses can operate in certain spectrum bands, while SUs without licenses seek for access opportunities for transmissions. When cooperation is performed between users, e.g., cooperation between SUs or cooperation between SUs and PUs, the users' service quality or system performance can be significantly improved, and this type of network is referred to as cooperative cognitive radio networks.

Historical Background

With proliferation of wireless devices and services, the demand on spectrum resources keeps increasing dramatically. As a type of natural and limited resource, spectrum is conventionally managed using a static allocation policy, where different portions of spectrum are licensed and allocated to different wireless systems for exclusive access. However, this static spectrum allocation policy can result in spectrum wastage, resulting in the issues of low spectrum utilization and spectrum scarcity. To resolve those issues and accommodate the ever-increasing spectrum demand, cognitive radio network emerges, where the SUs without licenses can opportunistically access temporally unused spectrum owned by PUs. As one of the enabling technologies, spectrum sensing proposed by Joseph Mitola in 1999 (Mitola and Maguire 1999), is to identify unused spectrum bands and protect normal operations of PUs from harmful interference. As the first standard for cognitive radio, IEEE 802.22 standard (Cordeiro et al. 2005) released in 2011 also includes spectrum sensing as a vital key component. Popular methods for spectrum sensing include matched filter detector, energy detector, cyclic feature detection, and so on (Yucek and Arslan 2009).

However, due to wireless fading and shadowing as well as limited sensing capacity, spectrum sensing performance of individual users can sometimes be unsatisfactory, adversely affecting the performance of CRNs. To address these issues, user cooperation is adopted to overcome the limitations of individual spectrum sensing, which can help better identify and explore unused spectrum for the SUs.

Foundations

Spectrum sensing is of great significance in CRNs, to detect idle spectrum bands and avoid harmful interference to PUs. Because of potential fading and shadowing, e.g., the SU might be in severe fading or shadowed by buildings, sensing errors can occur. To deal with these problems, user cooperation has been conducted in cognitive radio networks (Zhang et al. 2015). According to the participants of PUs, user cooperation can be conducted in two main forms, i.e., cooperation among SUs and cooperation between SUs and PUs. For instance, SUs can cooperatively perform spectrum sensing to improve detection performance, which is also known as cooperative spectrum sensing in the literature. Alternatively, SUs can act as cooperative relays for PUs to help enhance the PUs' transmission performance. In return, PUs grant certain access opportunities to SUs as rewards, which can be used by SUs to transmit their own data. In cases when SUs have no traffic, SUs can still cooperate with PUs to gain some rewards, such as credits, which could be spent in spectrum trading when they have data to send. Therefore, there exist various forms of cooperation in CRNs, which can be harnessed by SUs to explore spectrum access opportunities. To sum up, SUs themselves can perform cooperative spectrum sensing to better detect idle spectrum bands where PUs are idle, as shown in Fig. 1a. When PUs are detected active, SUs can act as cooperative relays for PUs to gain spectrum access opportunities or credits, depending on whether SUs have traffic to send or not, as shown in Fig. 1b.

- Cooperative spectrum sensing among SUs: Each individual SU conducts spectrum sensing and sends the results to a fusion center, where the received sensing results will be combined for making a decision using some fusion rules such as AND rule, OR rule, Majority rule, and so on (Ma et al. 2008; Zhang et al. 2014b; Akyildiz et al. 2011). Alternatively, SUs can also cooperate in a distributed way, where sensing results are exchanged among SUs to reach a consensus on spectrum availability. Cooperation among SUs can improve the detection performance for protecting PUs better and reduce the false-alarm rate for efficient use of idle spectrums, through exploiting spatial diversity and multiuser diversity.
- Cooperation with PUs for transmissions: Cooperative communication between users can improve transmission performance, such as throughput, energy efficiency, reliability, and security. Cooperation between SUs and PUs can improve the performance of PUs where SUs act as relays. As a reward, PUs grant some spectrum access opportunities for SUs' transmission in exchange for SUs' cooperation (Zhang et al. 2013; Simeone et al. 2008; Han et al. 2009; Zhang et al. 2014a). Suppose a primary system operates in a time-slotted fashion and a PU owns a period of time for transmission. The PU can divide the whole period into three portions, and SUs and PUs cooperate in a three-phase fashion accordingly. Specifically, in the first two phases, the SU acts as either a cooperative relay for enhancing the PU's performance. Then, the PU grants the last phase to the SU for access. Consequently, a "win-win" situation is achieved, where both PUs and SUs get benefits.
- Cooperation with PUs for credits: When SUs have no data to send, for the above schemes, SUs may have no incentive to collaborate with PUs. Since different parties can trade or exchange spectrum resources in spectrum trading, SUs can still gain some spectrum access opportunities in such a case. Specifically, SUs can request credits as

Cooperative Cognitive Radio Networks, Fig. 1 Cooperation in cognitive radio networks. (a) Cooperative sensing. (b) Cooperative relaying

compensations for their cooperation with PUs to improve PUs' performance. The credits earned through cooperation with PUs can be utilized by SUs later in spectrum trading (Niyato and Hossain 2008) when they have traffic.

With the above three forms of cooperation, SUs can efficiently and effectively explore spectrum access opportunities. When SUs have no data to send, through cooperation with active PUs, they can first gain a certain amount of credits and then use those credits in spectrum trading for access. When SUs have traffic to serve, SUs can collaboratively sense spectrum to identify the unused spectrum reliably and efficiently. In cases when PUs are detected active and no idle spectrum bands are available, the SUs can gain some spectrum access opportunities by serving as cooperative relays for PUs.

Key Applications

Cooperative cognitive radio networks can improve spectrum utilization and help SUs to better detect and utilize spectrum access opportunities. It can support many emerging applications or services, such as Internet of things, cognitive radio sensor networks, mobile

networks, and vehicular networks, where devices can harness cooperation and cognitive radio to accommodate large number of devices and achieve higher transmission rate.

Cooperative Localization in Wireless Sensor Networks

Xiufang Shi

[Collaborative sensor network localization](#);
[Cooperative positioning in wireless sensor networks](#); [Relative localization](#)

Definition

Cooperative localization in wireless sensor networks (WSNs) refers to estimating the sensor nodes' locations using pairwise location-related measurements. These measurements are not limited to the ones between the unknown-location nodes and the known-location nodes (i.e., anchors or beacons) and also include the ones between neighboring unknown-location nodes.

Historical Background

Cooperative localization was firstly proposed for the positioning with mobile robots (Kurazume et al. 1994) such that the positioning information can be obtained without using the landmarks in the environments. This concept was then applied in WSNs, where sensor node localization is of great significance since in many cases the sensed data become meaningful only when they are correlated with the location information. Considering that the sensor nodes are generally of low cost and low power, it is unrealistic to equip each node with the widely used Global Positioning System (GPS) module, which is too expensive and of high-energy consumption. Therefore, in many scenarios, only a small number of nodes are deployed at known locations or equipped with GPS modules, and the remaining majority nodes need to be localized. The known-location nodes, which are often called anchors, play as references for sensor node localization. Due to the short communication/sensing range of sensor nodes, most sensors have insufficient connections with anchors for location estimation. Hence, the connections between the neighboring unknown-location nodes are also utilized in localization.

Foundations

Measurements

The goal of cooperative localization is to find the locations of all the sensor nodes using the pairwise measurements from the inter-node links.

The widely used location-related measurements include (Patwari et al. 2005; Mao et al. 2007):

- *Received Signal Strength (RSS)*. In an ideal free-space environment, the received power decays in proportional to the inverse square of the transmitter-receiver distance (Rappaport et al. 1996). In real-world channels, RSS measurements are with environment-dependent errors, which mainly come from multipath signals and shadowing. RSS is typically modelled using the ensemble mean received power, which is in proportional to the logarithm of the transmitter-receiver distance. RSS measurements are of low device costs, whereas the estimation accuracy of transmitter-receiver distances from RSS measurements is low.
- *Time of Arrival (TOA)*. One-way propagation time and roundtrip propagation time measurements are both known as TOA measurements. Distance between neighboring nodes can be estimated from TOA measurement. One-way propagation time measurement requires accurate clock synchronization between the transmitter and the receiver, while roundtrip propagation time measurement has no synchronization problem. In practical environments, the accuracy of TOA measurements can be degraded by non-line-of-sight (NLOS) propagation of wireless signals.
- *Time Difference of Arrival (TDOA)*. TDOA measurement denotes the time difference of the transmitter's signal at different receivers. Distance differences between the transmitter and a number of receivers can be estimated from TDOA measurements. TDOA measurement requires clock synchronization between the receivers, and its accuracy is also affected by multipath and NLOS propagation.
- *Angle of Arrival (AOA)*. AOA measurements provide relative directional information between neighboring nodes. AOA estimation requires multiple antenna elements, which will increase the nodes' hardware cost. The accuracy of AOA measurements is affected by the directivity of the antenna, shadowing, and multipath reflections.
- *Connectivity*. The connectivity information indicates that a node is in the communication range of another node. It can define a proximity constraint between two nodes and be exploited for localization.

Localizability

Localizability means that the sensor network is uniquely localizable, i.e., all the sensor nodes in the network can be uniquely positioned in a global sense. The localizability analysis is based on graph theory by formulating the sensor network as a graph $G = (V, E)$, where V is the vertex set representing all the nodes in the network and E is the edge set representing all the inter-node links within the communication range. Each node can get location-related measurements from links to its neighbors.

For range-only network localization in two-dimensional space, if the distance measurements are noiseless, a sensor network is localizable if and only if the graph G is *generically globally rigid* and there are at least three noncollinear anchors (Aspnes et al. 2006); if the distance measurement errors are not too great, on the premise of *generically globally rigid* graph and at least three noncollinear anchors, the network will be approximated localizable, and the sensor nodes' location estimates can be near the real values (Anderson et al. 2010).

For bearing-only network localization in two-dimensional space, if the bearing measurements are noiseless, a sensor network is localizable if and only if the graph G is *parallel rigid* and there are at least two anchors; if the bearing measurement errors are small enough, on the premise of *parallel rigid* graph and at least two anchors, the network will be approximated localizable, and the sensor nodes' location estimates can be near the real values (Shames et al. 2013).

Fundamental Limits

Cramer-Rao lower bound (CRLB) is a useful tool in analyzing the fundamental limits of localization accuracy. CRLB can provide a lower bound on the variance of unbiased location estimates. It is derived from Fisher information matrix (FIM),

which can measure the amount of information that comes from the measurements. For cooperative localization in a network, FIM can be written as $\mathbf{J} = \mathbf{J}_A + \mathbf{J}_C + \mathbf{J}_P$, where $\mathbf{J}_A$, $\mathbf{J}_C$, and $\mathbf{J}_P$ respectively denote the localization information from anchors, sensors' cooperation, and a priori knowledge of the sensors' locations (Shen et al. 2010). This intuitively shows that sensors' cooperation can improve the localization accuracy. FIM for a network is a matrix of high dimensions about all the sensor nodes' locations. With regard to an individual node's location, its position error bound can be calculated using equivalent FIM (EFIM), which retains all the necessary information to determine the CRLB of this node's location (Shen and Win 2010). In cooperative localization systems, CRLB is closely related to network geometry, measurement type, measurement errors, and unknown nuisance parameters, e.g., NLOS bias. Such performance bounds can provide guidance to system designers in network deployment and measurement type selection, and can also play as benchmarks for evaluating the performance of localization algorithms.

Algorithms

Algorithms for solving the cooperative localization problem can be categorized in several different ways (Buehrer et al. 2018).

- Measurement type:* Based on the measurement being used, localization algorithms can be classified as connectivity-based, distance-based, angle-based, and hybrid methods. Connectivity-based localization (Niculescu and Nath 2001; Shang et al. 2004; Lederer et al. 2009) is of low device cost and computational complexity, while its localization accuracy is also low. Distance-based localization (Soares et al. 2015; Shi et al. 2017) and angle-based localization (Zhong et al. 2014; Lin et al. 2016) can provide more accurate location estimation, while they have higher device requirements and computational complexities. Hybrid approaches (Eren 2011; Ding et al. 2012) utilize multiple measurement types such as distance and angle, which thus
- can improve the localization accuracy of those using single measurement type.
- Centralized versus distributed:* Based on where the computation is performed, localization algorithms can be classified as centralized algorithms and distributed algorithms. In centralized algorithms (Biswas et al. 2006; Shang et al. 2004; Gholami et al. 2013), all the anchor locations and measurement data are forwarded to a processing center, and the locations of unlocalized nodes are jointly estimated at this center. In distributed algorithms (Safavi et al. 2018; Zhong et al. 2014; Zhu and Ding 2011; Soares et al. 2015; Lin et al. 2016), the location estimation is spread over the network, and each unlocalized node estimates the location by itself through local information exchange with its neighboring nodes. Centralized algorithms utilize information about the entire network and generally can provide more accurate estimates than distributed algorithms by optimizing some global objectives, e.g., maximizing the likelihood functions of the locations and minimizing the least square errors. Whereas, centralized algorithms are not robust to the processing center failure. Distributed algorithms are more scalable and robust to node failures, while they have higher requirements on the computation ability of unlocalized nodes.
- Deterministic versus probabilistic:* Based on the way of problem formulation, localization algorithms can be classified as deterministic algorithms and probabilistic algorithms. Deterministic algorithms (Biswas et al. 2006; Soares et al. 2015; Lin et al. 2016; Shi et al. 2017) assume that the locations are deterministic but unknown values; they obtain deterministic location estimates without additional information about the quality or the reliability of this solution. In probabilistic algorithms (Ihler et al. 2005; Wymeersch et al. 2009), the localization problem is formulated as a probabilistic inference problem to compute or approximate the probability distribution of each unlocalized node's location. Probabilistic algorithms can return a set of possible

location estimates preferably along with the weights quantifying the uncertainty or equivalently the reliability of the corresponding estimates. Probabilistic algorithms can provide more information about the location estimates, while their computational complexities are much higher than deterministic algorithms.

- *One shot versus tracking*: Based on whether the temporal information is utilized, localization algorithms can be classified as one shot estimation and tracking. In one shot estimation algorithms, the historical data are not utilized. In tracking algorithms (Kantas et al. 2012; Vaghefi and Buehrer 2017; Safavi et al. 2018), both the historical data and the sensors' motions are utilized. One shot algorithms can be applied to the localization of both the static sensors and mobile sensors, while tracking algorithms are generally applied in mobile sensor networks.

Key Applications

Cooperative localization plays an important role in many key applications of WSNs, such as environmental monitoring, animal tracking in biological research (Patwari et al. 2005), logistics (Patwari et al. 2005), etc. In these applications, the location information is of great significance, while GPS modules are undesirable because of high device cost and power consumption.

In recent years, with the advent of Internet of Things (IoT) and the fifth generation (5G) networks, the number of connected devices is expected to meet an exponential increase (Buehrer et al. 2018). The emerging technologies such as device-to-device (D2D) communication would enable the acquisition of D2D location-based measurements, which can be utilized in cooperative localization (del Peral-Rosado et al. 2017). Hence, IoT and 5G will result in a unique opportunity for cooperative localization (Buehrer et al. 2018). Accordingly, location-based services provided by IoT and 5G would benefit from cooperative localization.

Definitions

Coordinated Multipoint (CoMP) transmission and reception comprises a series of schemes that a user equipment (UE) is served simultaneously by several points to enhance the received signal quality. A *point* refers to a set of geographically co-located transmit antennas, such as the set of antennas at a cellular base station (BS). Note that different sectors of the same BS site are thought of as different points. In CoMP, the channel state information (CSI) and/or data needs to be shared among neighboring points to coordinate their transmissions in the downlink or jointly process the received signals in the uplink. CoMP can effectively turn otherwise harmful intra-cell or inter-cell interference into useful signals and achieve significant power gain. It is an effective tool to improve the coverage of high data rates, the cell-edge throughput, and also to increase system throughput.

Historical Background

CoMP is a special technique of base station cooperation. The history of base station cooperation can be traced back to the 1990s when the concept of *macro-diversity* was proposed. In macro-diversity schemes, one or more mobile stations transfer the same message simultaneously with multiple surrounding base stations to provide diversity against long-term and short-term fading. For example, in Code Division Multiple Access

(CDMA) networks, a mobile station can communicate simultaneously with several base stations by means of soft handoff, and it can select the best channel among those base stations at any given time by selection diversity. Both coverage and capacity can be increased by means of this scheme as shown in Viterbi et al. (1994). In order to further remove the inter-cell interference penalty, researchers in academia also proposed the idea of full base station cooperation, which means all the base stations in the network are connected to a central processing site. The central processing site is responsible for collecting all the channel and data information and controls the transmission and reception of all the base stations in the network. In this way, the whole network effectively becomes a multiple-input multiple-output (MIMO) broadcast/multi-access channel with distributed antennas in the downlink/uplink, respectively. Such a network with full base station cooperation has been considered for the uplink in Hanly (1996), where the received signals at each base station are combined together before decoding at a global decoder. Thus all received signals provide useful information, and the interference at each individual base station is utilized. For the downlink, the cooperative transmission of multicell base stations was investigated in Shamai and Zaidel (2001). The results show that if the power constraints of individual base stations are ignored, the cooperative downlink transmission is recognized almost identical to that of the MIMO broadcast channel.

Research in academia has also drawn considerable interest from industry and propelled the investigation of base station cooperation in the standardization bodies, especially the Third Generation Partnership Project (3GPP). In 3GPP Long-Term Evolution (LTE) Release 8, inter-cell interference coordination (ICIC) is supported by means of coordinating message exchanges between base stations via a standardized backhaul interface named X2. The aim of ICIC is to reduce inter-cell interference for neighboring users that belong to different cells by serving those users using different frequency resources. Base stations that support this feature can generate interference information for each

frequency resource and exchange the information with neighbor base stations through the X2 interface. By learning the interference status of its neighbors, each base station can allocate the radio resources and adjust the transmit power for their users to avoid inter-cell interference. The ICIC techniques are designed primarily for semi-static coordination due to limitations of latency in the X2 interface.

The CoMP technology was introduced to standardization by 3GPP LTE-Advanced in 2011. Compared to ICIC, CoMP techniques pursue more dynamic coordination, and it is one of the core features in 3GPP Release 11 (see 3GPP TR 36.819 2013). In that specification, the CoMP scheme description, deployment scenarios, and implementation aspects, such as control signaling and UE feedback, were specified. The backhaul requirement is one of the fundamental requirements in CoMP. The discussions of CoMP in 3GPP Release 11 are mainly based on ideal backhaul assumptions. The support of CoMP involving non-ideal backhaul and the backhaul requirements for CoMP were addressed in 3GPP Release 12 (see 3GPP TR 36.874 2013). Further enhancements to CoMP operations were introduced in 3GPP Release 14 (see 3GPP TR 36.741 2017), such as support of noncoherent joint transmission.

Key Applications

In traditional cellular networks, the signal quality of cell-edge users is significantly degraded compared to users in the cell center. This is mainly due to the co-channel interference from neighboring cells using the same frequency channel. CoMP transmission and reception is considered in 3GPP LTE-Advanced Release 11 as a tool to reduce inter-cell interference, boost received signal quality, and increase system throughput, especially for users at the cell edge. In 3GPP's terminology, a point is defined as a set of co-located antennas providing coverage in the same sector. Different points can refer to geographically separated base stations (BSs) or different sectors of the same BS site. The CoMP techniques dynam-

ically coordinate the transmission or reception of multiple points to provide joint scheduling of transmission as well as joint processing of received signals. In CoMP, a user equipment (UE) in the network is able to be served by two or more points. By having several BS sites or sectors to transmit or receive the same information and using specialized combining techniques, CoMP can utilize the interference constructively rather than destructively and turn the inter-cell interference (ICI) into useful signals.

In essence, the CoMP schemes can be divided into the following two major categories:

- Coordinated scheduling/coordinated beamforming (CS/CB):** In CS/CB schemes, a UE is transmitting or receiving signals to or from a single point at a given time and frequency channel. However, the communication is made with an exchange of control signals among several coordinated entities. In the downlink, CS/CB is characterized by the fact that multiple coordinated points only share channel information for the UE terminals, while the data packets that need to be conveyed to a UE terminal are available only at one point. The scheduling decision is coordinated among the transmitting points (TPs) that participate in the set of coordinating entities. When the TPs are equipped with multiple antennas, the multi-antenna TPs can adjust their beamforming coefficients to steer toward or evade certain UEs. The scheme of CB is illustrated in Fig. 1. Compared to the joint processing schemes, the CS/CB schemes have the advantage that the requirements for coordination across the backhaul network are considerably reduced. This is due to two reasons: first, each UE's data only needs to be directed to one TP; second, multiple TPs only need to coordinate scheduling decisions and details of beams. In the uplink, the scheme of coordinated scheduling minimizes interference by coordinating the scheduling decisions among the receiving points (RPs). Similar to the downlink case, different RPs coordinate with each other and only need to transfer the scheduling data.

Coordinated Multipoint Transmission and Reception, Fig. 1 Illustration of CB scheme. Solid ellipses represent intended signals. Dashed ellipses represent interferences, which are in the null space of beams

Coordinated Multipoint Transmission and Reception, Fig. 2 Joint processing schemes in the downlink. (a) Joint transmission. (b) Dynamic point selection

- **Joint processing (JP):** JP means that multiple points cooperate with each other and simultaneously transmit signals to or receive signals from UEs. For the TPs, the JP schemes can not only boost the received signal quality of the intended UEs but also actively cancel the interference to other UEs. In the downlink, there are two kinds of JP schemes for the downlink: joint transmission (JT) and dynamic point selection (DPS). In the JT scheme, two or more TPs transmit the

same message data on the same frequency and in the same subframe. When data is available for transmission at two or more TPs but only scheduled for transmission from one TP in each subframe, it is called DPS. The schemes of JT and DPS are illustrated in Fig. 2. Since multiple TPs transmit the same message signals simultaneously, the UEs' data need to be first transferred to those TPs before being transmitted to the UEs. Due to the requirement of sharing UEs' data

between multiple TPs before transmission, JP schemes place higher demand on the backhaul network (Zhao et al. 2013). In the case of uplink, it is possible to perform joint reception, which utilizes antennas at different sites to form a virtual antenna array when different BSs cooperate with each other. The signals received by different BSs are firstly exchanged through the backhaul and then combined to produce the final output signal.

In general, there is a trade-off between backhaul burden and the CoMP gain. The CS/CB schemes require less data to be transferred through the backhaul network, but resulting throughput gain is also less; the JP schemes have higher gains in network capacity at the cost of higher amount of UEs' data exchange in the backhaul.

Applications Scenarios

The applicability of the CoMP function is largely dependent on the backhaul's latency and capacity, which depends on the type of CoMP processing that can be applied and the associated performance. In order to account for the various possible network topologies and backhaul characteristics, the study of CoMP in 3GPP has focused on the following scenarios according to 3GPP TR 36.819 (2013):

- Coordination between the cells (sectors) controlled by the same macro base station, where no backhaul connection is needed;
- Coordination between cells belonging to different radio sites from a macro network;
- Coordination between a macrocell and low-power transmit/receive points within its coverage, each point controlling its own cell, i.e., with its own cell identity;
- The same deployment as the latter, except that the low-power transmit/receive points constitute distributed antennas (via RRHs) of the macrocell and are thus all associated with the macrocell identity

Definitions

Cyber-physical security in smart grid communications means to secure smart grid communications from a cyber-physical system point of view.

History Background

As widely considered to be the next generation of the power grid, smart grid has been proposed to fully upgrade the energy generation, transmission, distribution, and consumption. It can be defined as an informationized power grid that leverages information and communications technology (ICT) to automatically gather and act on meter data, in order to improve agility, reliability, efficiency, security, economy, sustainability, and environmental friendliness.

A variety of communication standards and technologies coexist in different communication networks of smart grid. Home area networks/business area networks/industrial area networks (HANs/BANs/IANs) are deployed within residential units, commercial buildings, and industrial plants for connecting multiple electrical appliances to smart meter through IEEE 802.15.4 (ZigBee), IEEE 802.11 (Wi-Fi), or power-line communication (PLC). Neighborhood area networks/field area networks (NANs/FANs) support communications among distribution substations and field electrical devices for power distribution system and microgrid operation. They connect multiple smart meters to data aggregate unit (DAU) through IEEE 802.11 (Wi-Fi), IEEE 802.16m [Worldwide Interoperability for Microwave Access (WiMax)], or cellular networks [e.g., general packet radio service (GPRS), 3G, and long-term evolution (LTE)]. Wide area networks (WANs) facilitate communications among bulk generation, power transmission system, and meter data management system (MDMS) through fiber-optic communication, microwave transmission, or cellular networks.

With the incorporation of cyber space such as ICT, smart grid becomes more open to and cyberly accessible from outside networks, such as Internet-based office networks and smart meters with two-way communication between suppliers and customers. Despite the advances, this integration also leads to new vulnerabilities of cyber-physical security, which has been reported as one of the main threats to the reliable operation of smart grid. Availability, integrity, and confiden-

tiality, also known as the CIA triad, are three of the fundamental security requirements of smart grid communications.

Confidentiality refers to the prevention of data access by unauthorized persons or entities. Smart grid communications have unintended consequences for customer privacy. Malicious attacks targeting confidentiality can be considered as privacy issues. Privacy issues have to be covered with the derived customer consumption data as they are created in metering devices. Consumption data contains detailed information that can be used to gain insights on a customer's behavior.

Integrity refers to preventing undetected modification of information by unauthorized persons or systems. For smart grid communications, this applies to information such as product recipes, sensor values, or control commands. Integrity is critical for smart grid monitoring and control, during the data collection and command notification processes, respectively. In particular, false data injection (FDI) attacks can alter the state estimation of the electrical grid and, thus, alter its operation. As a result, revenue losses are expected. On the other hand, false commands (e.g., breaker opening commands) can cause devastating effects on the electrical grid, such as large-scale blackout.

Availability refers to ensuring that unauthorized persons or systems cannot deny access or use to authorized users. For smart grid communications, this refers to all the IT elements of the plant, like control systems, safety systems, operator workstations, engineering workstations, manufacturing execution systems, as well as the communication systems between these elements and to the outside world. Malicious attacks targeting availability can be considered as denial-of-service (DoS) attacks. DoS attacks are a kind of resource consumption attacks, which send fast requests to a server or directly jam the communication channel. By compromising multiple smart meters, distributed DoS (DDoS) attacks can also be launched. Since the availability of data and commands are critical for electrical grid monitoring and control,

DoS/DDoS attack can significantly interrupt grid operation.

Key Applications

Taking FDI attacks, for example, which can circumvent bad data detection (BDD) and insert any bias into the value of the estimated state stealthily. Due to historical reasons, FDI attacks are also known as stealthy deception attacks, load redistribution attacks, malicious data attacks, data integrity attacks, and so on, proposed by different research groups at different time.

The concept of FDI attacks was first developed by Liu et al. (2009). After that, continuous works on constructing and/or defending against such attacks have been done in recent years, as a survey by Deng et al. (2017b). For the purpose of quantifying the potential threat to a power grid, two classes of security indices are introduced by Sandberg et al. (2010), corresponding to two different types of FDI attacks, namely, sparse attacks and small magnitude attacks, respectively. One of such security metrics is used by Teixeira et al. (2011) to show limitations of linear attack policies on the nonlinear AC power flow model. Besides, Teixeira et al. (2010) further propose a generalized approach to construct deception attacks on state estimation in smart grid, with specific target constraints. Dán and Sandberg (2010) consider clusters of meters at the same attack cost for the adversary to compromise and propose greedy algorithms for perfect and partial countermeasures against FDI attacks. The concept of load redistribution (LR) attacks was first introduced by Yuan et al. (2011) as a special class of FDI attacks. Kosut et al. (2011) investigate two different regimes of FDI attacks on state estimation in smart grid and investigate how FDI attacks will interfere electricity market operations, because the biased state estimation result will be used for economic dispatch. Xie et al. (2011) show that the adversary can launch FDI attacks for continuous financial arbitrage. e.g., virtual bidding at selected pairs of buses. Jia et al. (2011) consider making profit for the generator at a specific bus by launching FDI attacks on the

real-time market. Besides, Jia et al. (2012) further investigate three different scenarios: the adversary may have full, partial, or zero knowledge of real-time measurements. Bi and Zhang (2013) show that by fabricating a fake transmission congestion pattern, FDI attacks can manipulate real-time electricity price at any target bus. Bobba et al. (2010) explore how to detect FDI attacks: one way is to secure basic measurements which are selected strategically, while the other way is to verify state variables independently which are selected strategically. Kim and Poor (2011) investigate constructing FDI attacks on the power grid based on linearized measurement models and propose strategic countermeasures against such attacks, by either immunizing a small number of meter measurements or deploying phasor measurement units (PMUs). Giani et al. (2013) consider unobservable data integrity attacks on power systems and also present corresponding defense approaches by means of PMUs. Bi and Zhang (2011) propose countermeasures against FDI attacks by protecting critical state variables. In addition, Bi and Zhang (2014) further propose a mixed protection strategy, in case that either fails to obtain the defense objective. Göl and Abur (2013) identify the vulnerability of state estimation against cyberattacks and provide two PMU-based countermeasures, by either converting critical measurements to redundant ones or eliminating the leveraging effect of leverage measurements. Deng et al. (2017a) assume that whether or not a meter measurement could be compromised by an adversary depends on the defense budget deployed by the defender on the meter and design a least-budget defense strategy from this perspective, which is suitable for large-scale power systems.

As a typical cyber-physical system, smart grid communications are vulnerable to a wide variety of cyber and/or physical attacks. In literature, both cyber and physical attacks have been investigated. In addition to aforementioned cyberattacks, (Salmeron et al. 2004; Holmgren et al. 2007; Chen et al. 2011) have discussed the optimal allocation of defense resources against physical attacks. Recently, to demonstrate the vulnerability of smart grid to joint cyber and

physical attacks, Soltan et al. (2015) made the first attempt to consider an adversary disconnecting some transmission lines and blocking related information to the control center. Li et al. (2016, 2018) showed that cyberattacks could mask transmission line outages, even for local attacks with incomplete network information. Deng et al. (2017c) investigate coordinated cyber-physical attacks (CCPAs) in smart grid and present two new kinds of CCPAs, for which cyberattacks can accurately mask transmission line outages by replaying meter readings and utilizing PMU measurements, respectively. Countermeasures are developed against the two kinds of CCPAs, respectively, based on known-secure PMU measurement verification and the observation that cyberattacks cannot mask the impact of physical attacks on the physical space (i.e., the power system equivalent impedance) which can be online tracked. This research indicates that the vulnerability and security of smart grid communications must be revisited from a cyber-physical system point of view.

Cyclic Prefix-Free OFDM/OFDMA Systems, Design, and Implementation

Xiqing Liu
Department of Engineering Science, National Cheng Kung University (NCKU), Tainan City, Taiwan

Synonyms

Insufficient CP-OFDM/OFDMA systems; OFDM/OFDMA system without CP; Reduced guard interval OFDM/OFDMA

Definitions

CP-free OFDM/OFDMA system refers to an orthogonal frequency-division multiplexing

(OFDM) system or an orthogonal frequency-division multiple access (OFDMA) system, without insertion of cyclic prefix (CP) at the transmitter.

History Background

With an increasing demand for a higher data rate, such as 5G, more bandwidths will be required, which makes transmit signals extremely sensitive to inter-symbol interference (ISI) in a multipath channel. Orthogonal frequency-division multiplexing (OFDM) or orthogonal frequency-division multiple access (OFDMA), working as a multi-carrier transmission scheme, receives much attention due to its ability to combat ISI. A common approach to tackle ISI for an OFDM/OFDMA system is to insert a cyclic prefix (CP) at the beginning of every block before transmission. As long as the length of CP is made longer than channel delay spread, ISI will only occur within the CP period. After CP removal at the receiver, the data can be recovered successfully. However, the CP-based OFDM/OFDMA has to pay an expensive cost, that is, a loss of spectral efficiency, which will be one of the most serious limitations in futuristic high-rate wireless applications. In 3GPP LTE standard (3GPP TS 36.104 V13.2.0 2016), about 25% of an OFDM/OFDMA block is consumed by extended CP, and this is definitely a heavy price for the increasingly scarce spectrum resource.

To increase the spectral efficiency, the simplest method is to prolong the length of an OFDM/OFDMA block. The block length is determined by the symbol (such as the QAM symbol and the PSK symbol, etc.) time and the number of subcarriers. Prolonging the symbol time will reduce data rate, whereas increasing the number of subcarriers may result in a serious peak to average power ratio (PAPR) problem (Goldsmith 2005) and a high complexity in FFT/IFFT implementation (Sohn 2014), and what is more important is that the length of an OFDM/OFDMA block is limited by the channel's coherent time. Generally, the minimum

interval between two pilot signals is the block length. If the block length is longer than the coherence time, it will be difficult to obtain the accurate channel state information (CSI) in time via the existing channel estimation techniques. As a result, the receiver will suffer from a serious error when performing the coherent detection. In terms of analysis given above, it can be known that CP insertion will surely become a performance bottleneck in future OFDM/OFDMA systems due to its significant loss in spectral efficiency, and the CP-free OFDM/OFDMA addressed in this section is believed to be more competitive than CP-OFDM/OFDMA in future wireless applications.

The spectral efficiency degradation caused by CP insertion poses a challenge to the traditional OFDM/OFDMA systems and attracts lots of efforts to solve it. As the length of a CP is mainly decided by the length of channel impulse response (CIR), many works investigated CIR shortening schemes as an effort to reduce the CP length. More details can be found in Zhang et al. (2003), Zhang and Qin (2010), Meng et al. (2008), and Lindqvist and Fertner (2011). Also, CIR may be different in various links and may change with time, and hence adjusting CP length to the current channel conditions is beneficial in terms of achievable data rate. In Tonello et al. (2010) and Huang and Rao (2012), an online CP adaptation method was developed for determining optimal CP length via estimating the channel statistics during transmission, while in this section, two kinds of CP-free OFDM algorithms will be introduced in detail, i.e., symbolic cyclic shift equalization (SCSE) and time domain precoding (TDP).

Symbol Cyclic Shift Equalization

Figure 1 is the block diagram of the SCSE-OFDM. It can be seen that a quadrature amplitude modulation (QAM) mapper maps the i th binary input $\mathbf{b}_i^T$ into a block of QAM symbols $\mathbf{S}_i^T$. Then, $\mathbf{S}_i^T$ is sent into a serial to parallel (S/P) converter before IFFT module. Thereafter, an IFFT is performed on $\mathbf{S}_i$ to generate an OFDM

**Cyclic Prefix-Free
OFDM/OFDMA Systems,
Design,
and Implementation,**

Fig. 1 This is the block diagram of SCSE-OFDM system, including its transmitter and receiver

block, i.e., s_i , and then s_i go through a parallel to serial converter (P/S). After that, s_i^T will be sent into the channel. Here the baseband discrete multipath channel is considered.

Having experienced multipath propagation, the i th block of the received signal is r_i^T . Send r_i^T to S/P to get r_i , and then perform SCSE algorithm on r_i before FFT. SCSE is formed by decision feedback equalization (DFE) and CP regeneration (CPR). Specifically, DFE is implemented first to suppress ISI, yielding $\hat{g}_i$, and then $\hat{g}_i$ is fed into CPR to get $\hat{r}_i$. After SCSE, the newly constructed block will be sent to FFT and P/S to get $\hat{q}_i^T$. To remove the flat fading gain, a one-tap frequency domain equalization (FDE) needs to be implemented on $\hat{q}_i^T$ before decision device. After making the decision, a QAM demapper translates the recovered QAM symbols $\hat{S}_i^T$ into recovered binary bits $\hat{b}_i^T$.

Through the description given above, SCSE algorithm is the most concern, and Fig. 2 presents the main idea. Assume two consecutive blocks are considered, and the second block is the interest. It can be seen after multipath propagation, the ISI is the tail of the previous block, and it will be eliminated by the DFE, leaving a “Gap.” CPR pads this “Gap” before FFT. Here the block

is called the first OFDM block as it is preceded by a null period, whose length is at least equal to channel’s delay spread, and thus the interference from its previous blocks cannot be seen by the current OFDM block. However, after DFE, the different linear shifts induced by multipath propagation produce a “Gap” in the multipath return, which will destroy the orthogonality between the subcarriers if feed the block to FFT directly (Malkin et al. 2008). The reason is that FFT/IFFT is a cyclical algorithm for time/frequency conversion, which will lead to unrecovered distortion if the input blocks are linearly shifted in its processing interval (Lyons 2011). Thus, although the ISI is removed from the block, CP still should be generated. The process to generate the CP is called CP regeneration (CPR), and DFE plus CPR is named as symbol cyclic shift equalization (SCSE). With the help of SCSE, the linearly shifted blocks can be turned into cyclically shifted blocks.

Without loss of generality, assume the i th ($i = 2, 3, \dots$) OFDM block is the interest. As shown in Fig. 1, SCSE starts with the DFE procedure for ISI elimination. Assume when performing SCSE algorithm on the i th OFDM block, the detection of the $(i - 1)$ th OFDM block has

Cyclic Prefix-Free OFDM/OFDMA Systems, Design, and Implementation, Fig. 2 A schematic diagram with respect to SCSE algorithm with two consecutive OFDM blocks

been completed. Therefore, with the CSI known by the receiver, the tail of the $(i - 1)$ th OFDM block can be reconstructed, which is defined as $\hat{\mathbf{d}}_i$ in Fig. 1. Mathematically, the DFE can be expressed by,

$$\hat{\mathbf{g}}_i = \mathbf{r}_i - \hat{\mathbf{d}}_i. \quad (1)$$

Theoretically, ISI can be eliminated completely with the help of DFE, if no CSI error is introduced. However, after DFE, a “Gap” is produced between the neighboring OFDM blocks. As mentioned earlier, the DFE-processed “Gap” will result in serious ICI after the blocks have been sent into FFT, and padding the “Gap,” termed as CPR, is an important step.

For simplicity, the signal processing of the CPR algorithm will be illustrated with the help of an example presented in Fig. 3. Assume an OFDM block contains four symbols, which expe-

riences a two-ray multipath channel. The receiver is assumed to achieve synchronization with the first path to arrive, and the second block is the multipath return, whose delay equals to one sample time.

Step 1: The channel gains are assumed to be known by the receiver, and thus the first sample is utilized to estimate the first symbol in Path 1.

Step 2: Subtract “①” from the second sample, and the “①” in Path 0 can be got. Divide it by channel gain of Path 0, and then multiply by the channel gain of Path 1 to achieve the estimation of “①” in Path 1. In this way, all the values of “①” and “②” can be acquired.

Step 3: Having acquired “①,” subtract it from third sample to yield the “②” in Path 0, which is then used to estimate “②” in Path 1.

Step 4: In this step, “②” will be subtracted from the fourth sample, and the estimation of “③” in Path 0 will be got. Next, the estimated “③” is

Cyclic Prefix-Free OFDM/OFDMA Systems, Design, and Implementation, Fig. 3 The signal processing of an example with respect to CPR algorithm. Here “ $\textcircled{n}$ ” ($n = 0, \dots, 3$) refers to the n th symbol in an OFDM block

used to estimate the symbol beyond this detection interval, i.e., the fourth symbol in Path 1.

Step 5: After Steps 1–4, the estimations in all of the balls can be available. Specifically, the fourth symbol in Path 1, i.e., “ $\textcircled{3}$,” exceeds the detection interval, which can be regarded as the CP signal and will be fed into the “Gap” to construct the cyclically shifted OFDM block. Finally, send the new-constructed OFDM block into the follow-up FFT processor.

It can be observed from Fig. 3 that all the balls will be taken into the calculation to estimate CP signal. If an OFDM block contains a larger number of symbols, more calculation steps will be required. Therefore, to perform CPR, its high computational complexity will be a challenge for practical applications. To tackle this issue, Liu et al. (2017b) develop a low complexity algorithm for CPR implementation by constructing the conjugation symmetrical OFDM block at the transmitter.

Though SCSE can help an OFDM system to remove CP in a multipath channel, it has some drawbacks. For the DFE scheme, the decision error will inevitably occur due to fading, noises, impaired CSI, etc. If the decision error is conveyed to the “Gap,” the polluted gap will spread the error to the detection of following blocks, degrading the bit error rate (BER) performance. In addition, in some scenarios, where the power

of the first path to arrive is relatively weak, the estimation error produced by CPR can also degrade the BER performance since the gain of the first path to arrive always serves as the denominator to estimate the symbols in other paths. Moreover, detection delay caused by SCSE poses a challenge for the hardware, especially in a high data rate scenario. To deal with these issues, in the next subsection, a time domain precoding (TDP) algorithm designed for CP-free OFDM system will be introduced, and the mathematical derivations will be also given to validate its feasibility.

Time Domain Precoding

Figure 4 is the block diagram of the TDP-OFDM. As shown in Fig. 4, $\mathbf{b}_i^T$ is the binary bit input. QAM mapper will map the binary bit sequence into a block of QAM symbols, defined as $\mathbf{S}_i^T$. Next, $\mathbf{S}_i^T$ is fed into S/P and IFFT to generate $\mathbf{s}_i = \mathbf{F}^{-1}\mathbf{S}_i$, in which $\mathbf{F}^{-1}$ denotes the IFFT matrix (Lyons 2011). After IFFT, perform TDP algorithm on $\mathbf{s}_i$ to get $\mathbf{w}_i$. The precoding matrix $\hat{\mathbf{X}}$ is formed by,

$$\hat{\mathbf{X}} = \hat{\mathbf{H}}^{-1}\hat{\mathbf{H}}_{\mathbf{C}} \quad (2)$$

Cyclic Prefix-Free OFDM/OFDMA Systems, Design, and Implementation, Fig. 4 This is the transmitter block diagram of the proposed TDP-OFDM system

where the matrices of $\hat{\mathbf{H}}$ and $\hat{\mathbf{H}}_C$ can be acquired by linearly shifting and cyclically shifting the vector of $\hat{\mathbf{h}}$. Specifically, $\hat{\mathbf{H}}$ and $\hat{\mathbf{H}}_C$ can be expressed by,

$$\hat{\mathbf{H}} = \begin{bmatrix} \hat{h}(0) & 0 & \cdots & \cdots & \cdots & 0 \\ \vdots & \ddots & \ddots & & & \vdots \\ \hat{h}(L-1) & \ddots & \ddots & & & \vdots \\ 0 & \ddots & \ddots & \ddots & & \vdots \\ \vdots & \ddots & \ddots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & \hat{h}(L-1) & \cdots & \hat{h}(0) \end{bmatrix}_{M \times M} \quad (3)$$

and

$$\hat{\mathbf{H}}_C = \begin{bmatrix} \hat{h}(0) & 0 & \cdots & 0 & \hat{h}(L-1) & \cdots & \hat{h}(1) \\ \vdots & \ddots & \ddots & & \ddots & \ddots & \vdots \\ \hat{h}(L-2) & \ddots & \ddots & & \ddots & \ddots & \hat{h}(L-1) \\ \hat{h}(L-1) & \ddots & \ddots & & \ddots & \ddots & 0 \\ 0 & \ddots & \ddots & \ddots & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & \hat{h}(L-1) & \hat{h}(L-2) & \cdots & \hat{h}(0) \end{bmatrix}_{M \times M} \quad (4)$$

where $\hat{\mathbf{h}} = [\hat{h}(0), \cdots, \hat{h}(L-1), 0 \cdots, 0]^T$ is the CSI vector with length extended to M and $\hat{h}(l)$ channel gain of Path l ($l = 0, \cdots, L-1$). Here M and L ($L < M$) refers to the lengths of the block and the CIR, respectively. It can be seen that $\hat{\mathbf{H}}_C$ is a cyclic matrix with its columns shifted circularly (Meyer 2000). Due to the property of a cyclic matrix, we can have

$$\mathbf{F}\hat{\mathbf{H}}_C\mathbf{F}^{-1} = \hat{\Lambda} = \begin{bmatrix} \hat{\lambda}_0 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \hat{\lambda}_{M-1} \end{bmatrix} \quad (5)$$

in which $\mathbf{F}$ and $\mathbf{F}^{-1}$ denote FFT and IFFT matrix. $[\hat{\lambda}_0, \dots, \hat{\lambda}_{M-1}]$ represents the frequency response of $\mathbf{h}$ (Chen et al. 2009). To perform precoding scheme on $\mathbf{s}_i$, we will first make a multiplication to get $\mathbf{u}_i$, or $\mathbf{u}_i = \hat{\mathbf{X}}\mathbf{s}_i$. In Fig. 4, $\hat{\mathbf{H}}_{\text{tail}}$ refers to the tail of the channel matrix induced by multipath propagation, which is calculated via

$$\hat{\mathbf{H}}_{\text{tail}} = \hat{\mathbf{H}}_C - \hat{\mathbf{H}} = \begin{bmatrix} 0 & \cdots & 0 & \hat{h}(L-1) & \cdots & \hat{h}(1) \\ \vdots & \ddots & & \ddots & \ddots & \vdots \\ \vdots & & \ddots & & \ddots & \hat{h}(L-1) \\ \vdots & & & \ddots & & 0 \\ \vdots & & & & \ddots & \vdots \\ 0 & \cdots & \cdots & \cdots & \cdots & 0 \end{bmatrix}_{M \times M} \quad (6)$$

Next, use $\hat{\mathbf{H}}_{\text{tail}}$ and the buffer's output to *pre-eliminate* the interference from the transmit signal, and we can have

$$\mathbf{w}_i = \mathbf{u}_i - \hat{\mathbf{H}}^{-1}\hat{\mathbf{H}}_{\text{tail}}\mathbf{w}_{i-1}, \quad (7)$$

which can be divided into two parts, i.e., information signal ($\mathbf{u}_i$) and the interference elimination signal ($\hat{\mathbf{H}}^{-1}\hat{\mathbf{H}}_{\text{tail}}\mathbf{w}_{i-1}$). As shown in Fig. 4, after S/P and digital to analog converter (DAC), $\mathbf{w}_i$ will be modulated by radio-frequency carrier and then transmitted into channel through antenna $\mathbf{T}_x$.

The transmit signal experiences the multipath channel to arrive at the receiver, and we can have the i th received OFDM block as

$$\mathbf{r}_i = \mathbf{H}\mathbf{w}_i + \Upsilon_{i-1} + \mathbf{v}_i, \quad (8)$$

where $\mathbf{v}_i$ is the noise term and Υ_{i-1} is the ISI term. In a multipath channel, the interference is caused by the tail of the previous block, i.e.,

$$\Upsilon_{i-1} = \mathbf{H}_{\text{tail}}\mathbf{w}_{i-1}, \quad (9)$$

in which $\mathbf{w}_{i-1}$ denotes the $(i-1)$ th OFDM block, and with the result in (Eq. 7), $\mathbf{H}\mathbf{w}_i$ can be further written as

$$\begin{aligned} \mathbf{H}\mathbf{w}_i &= \mathbf{H}[\mathbf{u}_i - \hat{\mathbf{H}}^{-1}\hat{\mathbf{H}}_{\text{tail}}\mathbf{q}_{i-1}] \\ &= \mathbf{H}\mathbf{u}_i - \mathbf{H}\hat{\mathbf{H}}^{-1}\hat{\mathbf{H}}_{\text{tail}}\mathbf{w}_{i-1}. \end{aligned} \quad (10)$$

Substituting Eqs. 9 and 10 into Eq. 8 yields

$$\begin{aligned} \mathbf{r}_i &= \mathbf{H}\mathbf{u}_i - \mathbf{H}\hat{\mathbf{H}}^{-1}\hat{\mathbf{H}}_{\text{tail}}\mathbf{w}_{i-1} + \mathbf{H}_{\text{tail}}\mathbf{w}_{i-1} + \mathbf{v}_i \\ &\triangleq \mathbf{H}\mathbf{u}_i + \mathbf{v}_i. \end{aligned} \quad (11)$$

It is noted that the second equality holds up under the assumption the perfect CSI can be fed back to the transmitter. Then, send $\mathbf{r}_i$ to the FFT processor, and we can get

$$\mathbf{q}_i = \mathbf{F}[\mathbf{H}\mathbf{u}_i + \mathbf{v}_i] = \Lambda\mathbf{S}_i + \mathbf{F}\mathbf{v}_i \quad (12)$$

where $\mathbf{F}$ denotes the FFT matrix. After P/S, $\mathbf{q}_i^T$ is sent into one-tap FDE, decision device, and demapper in turn. Finally, we can get the recovered binary data $\hat{\mathbf{b}}_i^T$.

Performance Evaluation

In Fig. 5, the 3GPP LTE channel models were employed to evaluate the BER performance (3GPP TS 36.104 V13.2.0 2016), where the modulation type is 16QAM and the number of subcarriers is 1024. The channel models are extended typical urban (ETU) and extended pedestrian A (EPA). With the bandwidth of 100 MHz, the delay spreads of ETU and EPA channels are 500 and 41, respectively. For the CP-OFDM system, the CP length is made equal to delay spread. From Fig. 5 we can observe that TDP-OFDM and CP-OFDM have a similar BER performance, but BER performance of SCSE-OFDM is significantly poor, especially under the ETU scenario, where the first path is a relatively weak (3GPP TS 36.104 V13.2.0 2016) and CPR may bring considerable estimation error. On the other hand, CP-OFDM overcomes multipath

Cyclic Prefix-Free OFDM/OFDMA Systems, Design, and Implementation,
Fig. 5 The BER is the transmitter block diagram of the proposed TDP-OFDM system

interference by means of CP insertion, but paying a price of spectral efficiency degradation. In the comparison of spectral efficiency, SCSE-OFDM and TDP-OFDM are better than CP-OFDM. With 16QAM modulation, the spectral efficiency of TDP-OFDM or SCSE-OFDM is about 4 bps/Hz in either ETU channel or EPA channel. However, the spectral efficiencies of CP-OFDM in the ETU and EPA channels are about 2 bps/Hz and 3.8 bps/Hz, respectively.

The number of complex multiplication is used here to evaluate the computational complexity of SCSE and TDP. For SCSE, $\frac{M}{2}\log_2 M + ML$ complex multiplications are consumed in the DFE (Liu et al. 2017a; Cooley and Tukey 1965). Also, the number of complex multiplications needed by CPR is ML . Thus, to complete the detection of the i th OFDM block, the total number of complex multiplications required by SCSE is

$$\mathcal{O}_{\text{SCSE}} = M \left(\frac{\log_2 M}{2} + 2L \right). \quad (13)$$

Different from SCSE, the computational complexity of the TDP algorithm is mainly allocated at the transmitter. The number of complex mul-

tiplications required for inversion transform of $\hat{\mathbf{H}}$ is $M \log_2 M$ (Commenges and Monsion 1984). As shown in Eq. 2, $\hat{\mathbf{H}}^{-1}$ is multiplied by $\hat{\mathbf{H}}_C$ to construct the precoding matrix, producing the computational complexity of M^3 . Besides, the calculation of $\hat{\mathbf{X}} \times \mathbf{s}_i$ will require M^2 complex multiplications, and the calculation presented in Eq. 7 will cost $M^3 + M^2$ complex multiplications. Therefore, to detect the i th OFDM block, the total number of complex multiplications consumed by the TDP algorithm is

$$\mathcal{O}_{\text{TDP}} = 2(M^3 + M^2) + M \log_2 M. \quad (14)$$

Be aware that the computational complexity of TDP is related to the channel coherence time. The calculations of $\hat{\mathbf{H}}^{-1}\hat{\mathbf{H}}_C$ and $\hat{\mathbf{H}}_{\text{tail}}\hat{\mathbf{X}}$ are just needed to be performed once within the same coherent time. Generally, the length of an OFDM block is much shorter than coherence time, and thus Eq. 14 holds an upper bound for TDP's complexity.

This contribution introduces two CP-free OFDM/OFDMA algorithms, i.e., SCSE and TDP. It is clear that the spectral efficiency of

the CP-free OFDM/OFDMA outperforms that of a traditional CP-OFDM/OFDMA. TDP is better than SCSE with respect to the BER performance owing to the decision error and the estimation error caused by DFE and CPR, respectively. However, TDP requires CSI must be fed back to the receiver timely to construct the precoding matrix, which poses a serious challenge to design a powerful feedback link, especially in a rapidly time-varying scenario. Moreover, TDP is power inefficient if it works in a deep fading channel (Goldsmith 2005). Therefore, a definite answer to which scheme is the optimal option is not available, as each scheme has its unique strength for a particular case.

Key Applications

At present, OFDMA has been widely studied and was chosen as the standard in the 3GPP LTE downlink multiple access scenario (3GPP TS 36.104 V13.2.0 2016). However, the CP degrades the spectral efficiency significantly, especially in a long delay spread channel; CP-free OFDM/OFDMA technology will be more competent than traditional CP-OFDM/OFDMA under the case where the spectral is the most concern. Additionally, CP-free OFDM/OFDMA systems may achieve more considerations in latency-sensitive wireless applications. Latency reductions in OFDM/OFDMA systems require substantial reductions in the block length, while CP holds the critical limitation to shorten an OFDM/OFDMA block, whose length is decided by the delay spread. Fortunately, in the CP-free OFDM/OFDMA systems introduced in this contribution, the multipath interference can be solved by equalization or precoding instead of CP, and the length of an OFDM/OFDMA block can be shortened without the limitation caused by CP. For this occasion, the CP-free OFDM/OFDMA may be a more proper choice than CP-OFDM/OFDMA in a latency-sensitive applications.

Definition

Longitudinal data, a common data type in the biomedical area, refer to the data where each participant has repeatedly measured values on the same variable at two or more time points. Time series data have more time points for each participant, (e.g., hourly, daily, weekly and monthly, etc.) compared to regular longitudinal data. Data streams refer to the real-time (on-the-fly) millisecond data for each participant generated from wireless biomedical devices such as sensors. Broadly speaking, time series and data streams are all longitudinal data with the difference in the frequency of time points when collecting data for each participant.

Data Aggregation

- [Application of Machine Learning in Wireless Sensor Network](#)

Data Analytics

- [Data-Driven Pattern Prediction](#)

Background for Longitudinal Biomedical Data Analytics

Common longitudinal data analytical models have been well studied in the statistical and biostatistical fields, ranging from common linear and nonlinear regression models (e.g., mixed or hierarchical models, mixture models) (McCulloch et al. 2008; Muthén et al. 2002; Skrondal and Rabe-Hesketh 2004) to emerging statistical learning (or machine learning) methods (e.g., lasso, random forests, artificial neural networks, MIFuzzy) (Murphy 2012; James et al. 2013; Hastie et al. 2009; Fang 2017).

Biomedical data can be small or big in terms of sample size. Big data are termed differently, called large-scale or high-dimensional data in statistics. Many emerging methods have been developed to analyze and understand these big data in the areas of genome, biomedical images, behavioral and administrative health data studies, and web-based and wireless health (Bishop 2006; Rajpurkar et al. 2017; Fang et al. 2015).

Key Applications of Data Analytics for Longitudinal Biomedical Data

Regularized approaches such as lasso (L1) and ridge (L2) are increasingly applied in longitudinal biomedical data, when the number of variables is large and potential overfitting is likely. Bias and variance trade-off issue needs to be considered, and usually the model reducing a substantial amount of variance is recommended even if a small amount of bias is introduced during the modeling process (e.g., Murphy 2012).

Validation is imperatively needed for biomedical data analytics. Numeric and graphic indices have been devised for specific methods, such as mixed and mixture models. Novel statistical learning methods are being developed for more complex longitudinal biomedical data, but not all have included vigorous validation procedure. Cross-validation, bagging, bootstrapping, and boosting methods are available and should be

applied in biomedical data analytics (Efron and Tibshirani 1993; James et al. 2013; Hastie et al. 2009; Zhang et al. 2016b).

Visualization methods such as those used in trajectory pattern recognition methods cannot just better present the high-dimensional longitudinal data but also assist in analyzing and validating patterns in biomedical data. More visual analytics in longitudinal studies are being developed. A visualization-aided validation has been studied to help behavioral trajectory pattern recognition of big longitudinal data (e.g., Fang and Zhang 2017; Zhang et al. 2016a). Figure 1 demonstrates that, by optimizing view angles, optimized 3D projection can better visualize patterns or clusters, compared to a random 3D projection (Fig. 1a, b). Figure 1a shows best 2D projection from optimized 3D view angle, while Fig. 1b indicates a poor 2D projection from random 3D view angle.

Multiple imputation-based fuzzy learning (MIFuzzy) is one of the most recently developed soft computing methods, used for learning the trajectory patterns of small or big complex data (e.g., high-dimensional, pattern overlapping, and error prone) with missing values in longitudinal random controlled trials and observational studies, including e-Health and mobile health (Fang 2017; Fang et al. 2009, 2010, 2011, 2012; Zhang and Fang 2016; Zhang et al. 2016a, b; Kim et al. 2017). MIFuzzy provides a comprehensive validation procedure, including fuzzy-logic based numeric indices, visual analytics, and simulation tools. The graphical user interface software for MIFuzzy is available online. It can be integrated with regularized approaches and other supervised learning methods such as neural networks. MIFuzzy is now being developed into a semi-supervised fuzzy learning method for prediction in biomedical studies (e.g., Gurugubelli et al. 2019).

Computational methods for real-time biomedical data streams are being developed, but these data are mostly downloaded and analyzed offline, as “historical” real-time data. Well-known ECG and EKG data streams are well studied, but data analytics for irregular behavioral data streams

Data Analytics for Longitudinal Biomedical Data, Fig. 1 (a) Best 2D projection from optimized 3D view angle. (b) Poor 2D projection from random 3D view angle

and multiple data streams are underdeveloped. Parameter trajectory description method based on descriptive statistics and slide window combined with supervised statistical learning methods such as K-nearest means and random forests are proposed for irregular behavioral data streams and multiple concurrent data streams which measure different bio-physiological parameters (Carreiro et al. 2015, 2016). However, a gap still exists between the conceptual promise of these approaches and the development of computationally efficient algorithms for the real on-the-fly event detection in these biosensor systems.

Conclusion

Common statistical models have been widely applied in biomedical studies. As more complex biomedical data are available, new statistical learning methods are being developed. Regularized approaches, validation, and visualization are key components for biomedical data analytics. Substantial efforts are needed to develop fast and accurate algorithms for analyzing behavioral and multiple concurrent biomedical data streams.

Data Center Network in Cloud Computing

Jiaju Qi and Long Zhao
BUPT, Beijing, China

Synonyms

Cloud computing; DCN

Definitions

Data center is composed of multiple parts, including a set of complex computer server equipment, the system of data communication connection, the system of data storage, the equipment of environment control and energy providing, the monitoring and safety equipment, etc. It is a collection of not only a series of computer server equipment but also a complex system running large-scale service applications, which can deal with large-scale computing data for business and organization.

DCN is the network applied to data center, which is composed of data centers and the connections among them. These connections include the structure of network topology, the equipment of routing and switching, and the protocols of connections. As to data center, its inner traffic can present typical features such as the increasing and high concentration of exchange data flow. Thus, the following requirements are needed in DCN, including ability on large-scale data, high expansibility, high robust, low configuration overhead, high bandwidth and efficient network protocol between the servers, flexible topology structure, link capacity control, traffic isolation, green energy saving and low cost, etc.

Cloud computing is an Internet-based computing mode. Based on cloud computing, information and resources of hardwares and softwares are available to computer servers and other devices (Wang et al. 2008). A typical cloud provider

provides a common network business application service, which can be interviewed by browser software.

Historical Background

If we only consider traditional data center, which is composed of computing module, storage module, communication module, and so on, DCN has a long history of development and can date from ENIAC. Then with the rise of cloud computing, SaaS (Kavis 2014) has realized the transition from the need for computing resources brought about by the infrastructure to the on-demand ordering model. DCN with cloud computing function has provided users with massive growth in data bandwidth resources. There are some DCN architectures designed for cloud computing. The tree-based DCNs like fat-tree and three-tier have been used broadly at last in the enterprise cloud (Fox et al. 2009). However they lack scalability (Meng et al. 2010), based on which some new DCN architectures have been proposed, such as fat-tree (Al-Fares et al. 2008) and VL2 (Greenberg et al. 2009).

Foundations

- The use of DCN in cloud computing:
 - Advantages

Since softwares and data are stored on servers in the data center, computing power can be used as a commodity to circulate via the Internet. As to cloud computing, DCN is an indispensable infrastructure of cloud computing data center. There are three advantages of DCN cloud computing services:

 1. DCN can effectively connect a large number of data centers to implement cloud computing services by applying some ingenious topology structure.
 2. DCN provides high communications between large-scale computer server equipment.
 3. DCN supports virtualization infrastructure, such as virtual machines, virtual switches, and virtual links, which gives DCN high scalability. The isolation and migration of the virtual infrastructure are very convenient for DCN.
 - Demands

In recent years, the demand and scale of cloud computing have increased rapidly. However, there are some shortcomings of DCN established by traditional networks, including the following problems: Infranet cannot carry mass traffic, Infranet is not fast enough, as well as the scalability of the network is inadequate. Application of DCN to cloud computing services should satisfy both availability and scalability. There are two new trends in the development of the DCN: the connection of DCN needs to be more simplified, and the service provided by DCN needs to be more stable.
 - Structures of DCNs for cloud computing

DCN for cloud computing uses a three-tier separate architecture from top to bottom, namely, cloud computing layer, virtual layer, and physical layer. Thereinto, we focused on cloud computing layer:

 - Cloud computing layer

The function of cloud computing layer provides an important foundation for cloud activities. In this layer, important modules such as big data, cloud service model, and cloud application can be implemented and applied. At the same time, the cloud computing layer also needs to monitor the virtual layer below in real time and allocate resources for the virtual layer.
 - Cloud service model

The cloud service model is a directly user-oriented module, which has three common definitions: infrastructure as a service, namely, IaaS; platform as a service, namely, PaaS; and software as a service, namely, SaaS (Kavis 2014):

1. Services to customers by IaaS are the applications run by operators on cloud computing infrastructure. Users can access it on a variety of devices through a client interface, such as a browser. Consumers do not need to manage or control any cloud computing infrastructure, including networks, servers, operating systems, storage, and so on.
2. Services to consumers by PaaS are the applications developed by customers using the development languages and tools provided.
3. Services to consumers by SaaS are utilized for all computing infrastructures, including CPU, internal storage, networks, and other basic computing resources, and users are able to deploy and run arbitrary software, including operating systems and applications.

For cloud service model, DCN has two challenges. One is that DCN needs centralized deployment and dynamic adjustment of network resource allocation, which leads to low efficiency. Second, it is difficult to charge in this business model.

– Big data analysis

Big data analysis and processing of cloud applications is also an important module of cloud computing layer. At present, DCN needs to support rapid processing of large amounts of data based on users' reliance on cloud demand. There are three requirements for DCN, the size of data, namely, volume; the size of data types, namely, velocity; and the speed of data processing, namely, variety. Volume requires that the nodes of DCN have abundant computing resources, including hardware resources, which can hold large amounts of data storage. Velocity requires that the nodes of DCN have data portability to complete tasks in different working environments. And variety requires that DCN's communication links have larger bandwidth to support high-

throughput data communications (Wang et al. 2015).

• Topology of DCNs for cloud computing

The design of topology structure for cloud computing needs to be improved for relieving central link blockage, expanding the network, and increasing end-to-end communication efficiency. There are three physical DCN architectures worth watching: hierarchical model, recursive model, and rack-to-rack model (Hammadi and Mhamdi 2014):

– Hierarchical model

Each layer of the hierarchical model uses different methods to control traffic flow by switches, which can effectively reduce network congestion. Among them, the most commonly used is three-tier DCN, namely, core, aggregation, and edge layers. The data flow starts from edge layer, passes through aggregation layer, and flows to core layers. Thanks to three-tier DCN's stable structure and ease of implementation, its use is more common. In addition, there are also fat-tree (Al-Fares et al. 2008), VL2 (Greenberg et al. 2009), and some other hierarchical architectures. They reduce the traffic load overhead at core layer to some extent and have high cost-efficiency. Hierarchical model is currently the most used DCN architecture, but it has some problems. One is that when the network is too large, the topology of hierarchical model architecture is too redundant, resulting in low scalability of the whole network.

– Recursive model

A switch and many servers constitute a cell, and the recursive model is composed of different cells. Different cells are connected by servers that perform better than normal ones and have higher computing speeds. Compared with hierarchical model, recursive model fully takes into account the importance of the implementation of high scalability, that is, the data center needs to be extended. In addition, recursive model has a higher utilization ratio than hierarchical model on the switch, resulting in lower cost and higher efficiency.

The structure of recursive model facilitates the implementation of load balancing. However, the performance of the recursive model depends too much on the bridge server, which leads to hard implementation in practice.

Key Applications

In the future, the development of IoT cloud computing will be more and more significant. As a necessary part of the cloud computing infrastructure, DCN for cloud computing has become a bridge among data centers and undertake the function of network computing and network storage.

Definitions

A data center (DC) is a facility used to house computer systems and associated components, such as servers (physical machines), storage and network devices (e.g., switches, routers, and cables), power distribution systems, and cooling systems.

A data center network (DCN) is the communication network that interconnects computer systems and associated components in a data center. Generally, a data center network can be described by the network topology, routing/switching equipments, and the network protocols.

Network virtualization is the process of combining hardware and software network resources and network functionality into a single, software-based administrative entity, a virtual network.

The data center network virtualization is a term that extends virtualization concepts such as abstraction, pooling, and automation to the data center network. Virtualization usually refers to

hardware virtualization, which typically applies the software or firmware called hypervisor to create multiple isolated and independent virtual machines (VMs) upon the underlying hardware resources (i.e., physical machine). Similar to hardware virtualization, network virtualization aims at creating multiple virtual networks (VNs) on top of a shared physical network substrate allowing each VN to be implemented and managed independently. A virtual network consists of a set of virtual networking resources, such as virtual nodes (including end hosts, switches, routers) and virtual links.

Historical Background

The conventional DCN is organized in a three-tier architecture that follows a multi-rooted tree-based network topology, where network switches are divided into three layers, namely, access, aggregation, and core layers, from the bottom up (Bari et al. 2013). As the lowest layer, the access layer consists of top-of-rack (ToR) switches that provide direct connectivity to the servers mounted on every rack. The switch in the aggregation layer is called aggregation switch (AS). Each AS forwards traffic from multiple access layer ToR switches to the core layer, while core layer switches are responsible for connecting the data center to the Internet. To improve the reliability of DCN, the adjacent layers are commonly connected with multiple links for redundancy.

A classic three-tier topology used in the DCN is fat-tree topology, which is a special type of Clos topology (Bari et al. 2013). The fat-tree topology is built of k power of deliveries (PODs), and each pod contains $k/2$ ASs and $k/2$ ToR switches. Each ToR switch is directly connected to $k/2$ servers, i.e., each POD contains $(k/2)^2$ servers. The core layer contains $(k/2)^2$ core switches where each of the core switches is connected to one aggregate layer switch in each of the PODs. The fat-tree topology can apply identical and cheap commodity products for all switches, and provide full bisection bandwidth in theory. However, the scalability is one of the major issues due to the limited number of ports

in each switch. Except for fat-tree topology, there are many other tree-based topologies adopted in the DCN, such as VL2, Aspen tree, Jellyfish, etc. (Xia et al. 2017). Moreover, the server-centric topology also plays an important role in DCN, e.g., DCell, BCube, and Scafida (Xia et al. 2017).

The conventional DCN is often constructed using layer-2 and layer-3 network, in which layer-2 networking is used within a POD (i.e., between access and aggregation layers) and layer-3 networking is used between PODs (i.e., between aggregation and core layers). In layer-2 networking, all switches in a POD form a layer-2 broadcast domain, which may lead to loop due to multipath redundancy. To deal with the problem, various spanning tree protocols (xSTP) are used to eliminate loops and prevent layer-2 broadcast storms, allowing only one of the redundant links to be used to forward traffic (Xia et al. 2017). Although this method reduces bandwidth efficiency, this layer-2 and layer-3 network architecture is the mainstream and works well in the conventional data center.

However, with the advent of cloud computing era, virtualization technology (commonly achieved by server virtualization) is widely used in data center. It is because virtualization technology can improve server utilization, allocate resources on demand, and reduce operation and maintenance costs. A physical machine can be virtualized to multiple VMs, and each VM runs independently with different MAC and IP addresses. Thus, data centers are required to support hundreds of thousands of servers (both physical and virtual machines). The main limitation of traditional DCN is scalability since commodity switches were not designed to handle a large number of VMs. In particular, switches have to maintain an entry in their forwarding information bases (FIBs) for every VM, which can dramatically increase the size of forwarding tables. Moreover, DCNs are also required to deliver high cross-section bandwidth to support a high volume of east-to-west traffic for cloud computing applications. Therefore, the traditional layer-2 and layer-3 network architecture fails to meet DCN requirements in the cloud computing era due to its low bandwidth efficiency.

In virtualized data center, a new requirement is that dynamic VM migration must be supported to maximize service reliability and deployment flexibility. However, VMs can only be migrated within a POD on layer-2 network. It is because if VMs are migrated across a layer-2 domain, their IP addresses have to be reassigned, which will make applications interrupted. Therefore, the need for a layer-2 network extension is required to support potentially millions of servers (VMs) in DCN, where VM migration can carry out in a large domain without being limited by the size of POD. Moreover, the non-blocking and low-latency data forwarding is required, and fat-tree topology must be supported to make optimal use of multiple data forwarding paths between switches. In this situation, the traditional layer-2 networking using xSTP protocols for a loop-free topology can lead to a large number of disabled links and result in performance deterioration.

Supporting multi-tenancy is another requirement for data center. A physical data center is commonly shared by multiple tenants. Each tenant has its own virtual data center consisting of a groups of VMs, storage and network resources. For the sake of security, traffic between tenants needs to be isolated. In traditional layer-2 networking, isolation is usually achieved through VLANs by dividing the network into multiple layer-2 broadcast domains. However, the number of supported tenants is limited by the number of VLANs defined in IEEE 802.1Q, i.e., a maximum of 4096 (IEEE 2014).

As can be seen above, the traditional DCN using layer-2 and layer-3 network architecture with xSTP and VLAN protocols cannot meet the scalability and management needs of large-scale virtual data center. Therefore, data center network virtualization emerges to deal with the problems.

Foundations

The foundations of data center network virtualization are various network virtualization techniques and network management techniques (Jain and Paul 2013; Alshaer 2015; Tatsuhiko et al.

2013). Network virtualization techniques can be divided into two classes, i.e., device virtualization and link virtualization (Wang et al. 2015).

Device virtualization refers to abstract physical hardware into multiple logical (virtual) switches and routers. A virtual switch (vSwitch) is a software application that acts as a layer-2 hardware switch providing communication between VMs and physical machines. vSwitches are usually implemented in hypervisors that run on physical machines to provide virtual environment for VMs. The key role of vSwitch is responsible for forwarding data packets between virtual network interface cards (NICs) of VMs and the physical NICs of host machine. That is, multiple NICs share the physical NICs with the help of vSwitch. The most common method to implement vSwitch is the virtual Ethernet bridge (VEB) and virtual Ethernet port aggregator (VEPA) techniques (IEEE 2012b). Both VEB and VEPA are designed to handle local VM-to-VM traffic, but they focus on different purposes. A VEB is a VLAN bridge aiming at switching the traffic of multiple VMs over an internal virtual network, while a VEPA forces the traffic of one or more VMs to be handled by an external switch. Moreover, VEPA is a simple extension to VEB that address many of the limitations with VEBs, such as traffic invisible and not configurable. An enhancement to VEPA is multichannel VEPA, in which Q-in-Q tagging mechanism is applied (IEEE 2006).

Another kind of device virtualization is to merge multiple physical switches at the same network layer on the logical switch without changing the existing physical network topology. This kind of technique brings many advantages, such as simplifying network structure, facilitating network protocol deployment, and improving network reliability and manageability. Benefit from it, the number of logical links between the logical switches can be reduced. Thus, the logical loops can be prevented, although loops may exist in the underlying physical network. However, this kind of technique is implemented privately by different vendors. Therefore, the products of different vendors cannot interoperate with each other. Some typical technologies are Huawei's cluster switch system (CSS), intelligent

stacking (iStack) and super virtual fabric (SVF), Cisco's virtual switching system (VSS) and fabric extender (FEX), H3C's intelligent resilient framework (IRF), VMware's vSphere distributed switch (VDS), etc.

Just as its name implies, link virtualization refers to the technologies that establish logical links between virtual network devices, e.g., VMs, vSwitches, etc. The key point of link virtualization is to use encapsulation techniques (e.g., tagging or tunneling) to build up overlay networks on the underlying physical network. The key objectives are to achieve location-independent addressing, scaling up the number of logical networks, providing network isolation for multi-tenant environment, etc. There are various levels of link virtualization technologies, which can be partitioned into several classes, such as layer 2 over layer 2 (L2oL2), layer 2 over layer 3 (L2oL3), etc.

There are various L2oL2 techniques, including provider bridge (PB, also known as Q-in-Q) (IEEE 2006), provider backbone bridge (PBB, also known as MAC-in-MAC) (IEEE 2008), provider backbone bridge traffic engineering (PBB-TE) (IEEE 2009), shortest path bridging (SPB) (IEEE 2012a), transparent interconnection of lots of links (TRILL) (Eastlake et al. 2011), etc. Among them, TRILL and SPB are the most popular techniques appropriate for DCN. TRILL is an Internet engineering task force (IETF) standard for layer-2 scalability. The frame of TRILL protocol introduces a TRILL header between the "outer" and "inner" Ethernet headers. The main fields in the TRILL headers are hop count and ingress and egress nicknames that are used for routing. TRILL network implements layer-2 routing by extending intermediate system to intermediate system (IS-IS) routing protocol (Eastlake et al. 2011), which is similar to the open shortest path first (OSPF) protocol in a layer-3 network. On a TRILL network, data packets can be forwarded using equal-cost multipath (ECMP) algorithm or along the shortest path, which can greatly improve the data forwarding efficiency and throughput of DCNs. Moreover, TRILL can prevent loops and speed up network convergence

in the layer-2 networking. To address the multi-tenancy issue, TRILL uses a 24-bit-long fine-grained label to identify tenants. For SPB, its core idea is similar to TRILL, which also use IS-IS protocol but with different packet encapsulation.

On the other hand, the L2oL3 techniques are also known as network virtualization over layer 3 (NVO3) techniques (Black et al. 2016). NVO3 presents a high-level overview architectural framework that identifies key functional components for data center network virtualization. Currently, four NVO3 techniques are the most popular and supported by the majority of vendors, i.e., virtual extensible local area network (VXLAN) (Mahalingam et al. 2014), network virtualization using generic routing encapsulation (NVGRE) (Garg and Wang 2015), stateless transport tunneling (STT) (Davie and Gross 2016), and generic network virtualization encapsulation (Geneve) (Gross et al. 2018).

VXLAN is an IETF specification that is designed to address the need for overlay networks within virtualized data centers accommodating multi-tenant environment (Mahalingam et al. 2014). VXLAN uses a MAC in user datagram protocol (UDP) encapsulation to enable L2oL3 overlay networks. Each overlay is termed as VXLAN segment and identified through a 24-bit VXLAN network identifier (VNI) specified in VXLAN header. Only VMs using the same VNI can communicate with each other, which can achieve the network isolation for multi-tenant environment. Compared to VLAN, VXLAN allows a larger number of virtual networks (up to 16 M VXLAN segments) to coexist within the same administrative domain. Due to the encapsulation, VXLAN is also considered as a tunneling scheme. The end point of the tunnel termed VXLAN tunnel end point (VTEP) is typically located within the hypervisor on the physical machine that hosts VMs. The VXLAN tunnels (i.e., outer header encapsulation) are known only to the VTEP, while they are transparent to VMs. Thus, it is required that VTEPs should know the association between VM's MAC and VTEP's IP address. To obtain this association, different types of control

schemes can be applied, e.g., either a learning-based control plane or a central authority-based lookup. The central authority-based method is commonly realized by software-defined network (SDN) technique, which will be discussed later.

Similar to VXLAN, both NVGRE and STT are competing specifications but using different encapsulated formats and terms. For example, NVGRE applies a MAC in IP encapsulation, while STT adopts a MAC in transmission control protocol (TCP) encapsulation. Since all three encapsulation methods mentioned above are proposed by different vendors, none of them are compatible with each other. Thus, Geneve is developed by IETF NVO3 working group to address the perceived limitations of the earlier specifications and support all of the capabilities of VXLAN, NVGRE, and STT.

In addition to its advantages, data center network virtualization also brings many other management issues, e.g., configuring and monitoring the huge number of virtual networks for different tenants. Thus, network management technologies are required to efficiently administer and manage network complexity. Network management is not a new topic for data center. In traditional data center, management functions typically reside outside the network in a management system, which interact with network elements via network protocols for management, such as simple network management protocol (SNMP). However, traditional network management systems can only provide limited functionality and flexibility.

Thus, the need for a programmable network has led to much interest in software-defined networking (SDN) technology, which emerges as a new paradigm that shifts network control plane from distributed protocols to a logically centralized controller. SDN helps in network virtualization. Benefited from SDN, flexible network management and rapid deployment of new functionalities can be easily achieved, which makes SDN widely used in data center. The SDN architecture are divided into three planes from top down, i.e., application plane, control plane, and data plan (SDN 2013). In the upper plane, SDN applications define the network requirements and control logic for each tenant, which are sent

to the SDN controller via northbound interface (NBI). As the core entity, the SDN controller is responsible for translating the requirements of SDN applications down to SDN switches and providing the SDN applications with an abstract view of the network. The interface between an SDN controller and an SDN switch is termed control to data-plane interface (CDPI), which provides programmatic control of all forwarding operations, capabilities advertisement, statistics reporting, and event notification. There are various network protocols that can be applied on CDPI, such as SNMP, network configuration protocol (NETCONF) (Enns et al. 2011), open vSwitch database management protocol (OVSDB) (Pfaff and Davie 2013), OpenFlow (OpenFlow 2015), OF-CONFIG (OpenFlow 2014), RESTCONF (Bierman et al. 2017), etc.

Key Applications

There are many key applications including but not limited to multi-tenant data center, data center with a large number of virtual networks, and virtual data center.

Definitions

Due to the unique requirements in data center networks (DCNs) such as large scale, high application diversity, high power consumption, strict reliability, etc., the design of infrastructure and operations in DCNs face significant technical challenges. Researchers have been working on respective areas including network topology, optical networking, wireless networking, network virtualization, etc.

Historical Background

The rapid expansion of Internet services make data centers (DC) become a key infrastructure

to promote this growing trend. A DC usually accommodates a large number of computation and storage nodes which are interconnected through a DC network (DCN). As the vital part of communication, DCN plays a key role in DC operation.

Foundations

DCN Infrastructure

Transmission Technology

The data transmission in a DCN can be implemented in a wired or wireless form. Most conventional DCNs are built with electrical cables or optical fiber. In recent years, researchers also work on incorporating wireless technologies in DCNs.

- **Wired DCNs:** For wired DCNs, electrical cables are most commonly used in data centers due to the advantages of convenient deployment and compatibility to the conventional network system. Twisted pair cables can provide transmission rate between 10 Mbps and 10 Gbps with different specifications. However, they often encounter the problems of length limit. In addition to electrical cables, optical fiber is also widely used in data centers. Optical fiber has higher bandwidth, smaller size, lighter weight, and lower power consumption, compared to electrical cables. Using techniques like WDM (wavelength division multiplexing), 100 Gbps transmission rate in optical links has been achieved (Jianjun et al. 2016).
- **Wireless DCNs:** Due to the limitations and problems in the existing wired DCNs, researchers have been working on incorporating wireless communication technologies in DCNs. Up to now, 60 GHz radio frequency (RF) and free space optics (FSO) are two candidate technologies which are mostly discussed.

Networking Topologies

In switch-centric topologies, switches are mainly responsible for network construction and data transmission. The switches are usually connected by hierarchy topologies and the servers are generally connected to the low-level switches at network edge. The most typical topology in wired DCN is the tree-based hierarchical topology.

In fat-tree topology, all switching elements are identical, which provides cheap commodity components for all switches in communication architecture. In addition, for any communication mode, there are some paths that will saturate all the bandwidth available to the terminal host in the topology. In practice, it may be difficult to achieve an oversubscription ratio of 1:1 because of the need to prevent packet reordering of TCP flows (Al-Fares et al. 2008).

VL2 is a practical network architecture that can be extended to support large data centers with uniform high capacity between servers, performance isolation between services, and Ethernet layer semantics. VL2 uses flat addressing to allow service instances to be placed anywhere in the network. Address resolution based on terminal system can be extended to large server pools without complication to the network control plane (Greenberg et al. 2009).

In Walraed-Sullivan et al. (2013), the author uses the Aspen tree as a technique to modify the hierarchical data center topology, enabling the switch to respond locally to faults, which reduces the convergence time and control overhead of fault recovery. Studies have found that reducing the convergence time of a topology for a given network size results in a proportional decrease to its scalability. On the other hand, reducing the convergence time without affecting scalability requires the introduction of additional switches and links.

In a server-centric topology, servers are used to compute, route, or relay data to each other. DCell is a network structure with many functions for data center network. It is a recursive structure, in which advanced DCells are made up of many low-level DCells. The DCell at the same level is completely connected to each other.

DCell is fault-tolerant because it has no single point of failure, and its distributed fault-tolerant routing protocol will execute routes close to the shortest path even if there are serious link or node failures. For all types of services, it also provides higher network capacity than traditional tree-based structures (Guo et al. 2008).

DCN Operations

Traffic Control

The path to forward packets in the DCN is determined by various protocols, such as spanning tree, VLAN, routing algorithm, and OpenFlow. In a data center network, routers need to go beyond Layer 2 and the interconnected network with different network addresses. There are also many routing algorithms designed for specific network topologies, such as DCell Fault Tolerant Routing for DCell, BCube Source Routing Protocol for BCube, and Traffic Aware Routing for Traffic Conn.

Data center services also require priority management. Priority management provides different qualities of service by processing packets according to packet-based priorities rather than arrival orders. When a packet arrives at a transmitting or receiving queue with a full buffer, it is discarded if its priority is less than or equal to the lowest priority. Otherwise, the packet with the lowest priority is discarded to make room for the new packet. When the port is idle, the packet with the highest priority is sent.

Service Latency

Some service in data centers face rigorous service latency requirement. D3 (deadline-driven delivery) in Wilson et al. (2011) introduces a deadline-aware rating allocation for flows. Flows with deadlines encode the desired rate in their TCP SYN packets. Inspired by the recommendation of managing network congestion through explicit rate control, D3 explores the feasibility of using deadline information to control the rate at which terminal hosts introduce traffic in the network. Specifically, applications open process expiration date and size information when the process starts. The terminal host uses this information to request

the speed of the router from the data path to the destination.

Network Maintenance

The maintenance of the DCN is required after deployment, in order to monitor the network, identify network failures, and carry out repair actions. Techniques for detecting and handling network failures are studied by researchers. In Wu et al. (2012), it is recommended that NetPilot automatically mitigates network failures rather than repair faults. NetPilot mitigates failures in the same way as the operator – by deactivating or restarting suspected violation components. NetPilot does not need to know the exact root cause of the fault. Instead, it is implemented by an intelligent trial-and-error. The core includes an Impact Estimator, which prevents excessive disruptive mitigation measures, and a fault-specific mitigation planner that minimizes the number of trials.

Key Applications

Data center networking techniques can be used in data centers to ensure the performance of data centers.

Definitions

The delay-tolerant networks (DTNs) are under the umbrella of mobile ad hoc networks, which are featured with the long latency and unstable wireless topology. In DTNs, the end-to-end transmission delay from one node to another can be measured in days due to the absence of the routing paths.

Data forwarding in DTNs, such as data ferry, typically adopts store-and-forward techniques: if there are no connections available at a particular time, the source node needs to store and carry the message until the next available node is encountered, and these encountered nodes further relay the contents until the destination in the same store-and-forward manner.

Historical Background

Traditional data forwarding protocols in mobile ad hoc networks include two categories: proactive and reactive routings. In proactive routings, forwarding routes are computed automatically and independent of traffic arrivals. Examples of proactive routings include the Destination Sequenced Distance Vector (DSDV) (Perkins and Bhagwat 1994) and Optimized Link State Routing (OLSR) (Dhurandher et al. 2010). These protocols are capable of computing routes for a connected graph. However, they cannot find a path to link nodes in a disconnected but dynamic graph, such as DTNs.

In reactive routings, routes are discovered on demand when traffic needs to be delivered to an unknown destination. Such routing protocols include the Ad-hoc On-demand Distance Vector (AODV) (Perkins and Royer 1999) and Dynamic Source Routing (DSR) (Wu 2002). In these systems, a route discovery technique is employed to determine a path to the destination. These on-demand routing protocols incur additional delay, and they work best when communication patterns are relatively sparse. In delay-tolerant networks, as with proactive protocols, these protocols only work for finding routes in a connected subgraph

of the overall DTNs routing graph. However, they fail differently to proactive protocols. In particular, they simply fail to return a successful route (from a lack of response), whereas proactive protocols can potentially fail quicker (by determining the requested destination is not presently reachable).

The data forwarding issue is the fundamental problem for delay-tolerant networks. To deliver messages in such networks, existing algorithms, such as Epidemic (Lindgren et al. 2003) and PRoPHET (Lindgren et al. 2003), use flooding or partial flooding with a probability. There is a high probability that any flooding may cause network congestion or high interference, which consumes further resources for processing and switching operations. Context-aware routing protocols, such as CAR (Musolesi and Mascolo 2009) and HiBOP (HiB 2007), utilize context information such as history, battery status, and changes to the rate of connectivity to compute delivery probabilities. One of the reasons for the above routing mechanisms to use flooding or partial flooding is the lack of routing information. Geographic characters are unreliable and not enough to route messages efficiently due to the nodes' mobility characteristics. However, given the dynamic nature of DTNs, it should take other characteristics into consideration as a viable and beneficial option when we look into ways of increasing efficiency.

Foundations

Vector Routing Protocol

Kang and Kim (2008) propose a vector routing scheme in delay-tolerant networks in which the nodes own location information to calculate their velocity and direction to destination, which reduces the overhead of routing without decreasing the delivery success ratio. In Kang and Kim (2008), a mobile node uses its current vector V_{cur} and history movement pattern to predict a future moving vector. If two nodes are moving in the same direction based on the moving vector, the replication of packets for both nodes is not efficient. On the other hand, if two nodes move

in different directions, it is necessary to forward packets to both nodes. In vector routing, nodes moving in an orthogonal direction have a higher packet replication frequency compared to nodes moving in similar or opposite directions.

Furthermore, the velocity factor has also been taken into consideration. If two nodes move in the same direction, but the first node is faster than the second, packets may be forwarded to the faster node instead of replicating the slower node again. Simulations conducted from the NS-2 platform demonstrated that vector routing has a similar delivery success ratio compared with epidemic routing, but with 28% less traffic than random way-point model and 38% less traffic than Manhattan mobility model.

Similarity-Based Mobility Pattern-Aware Routing Protocol

Yin et al. (2009) propose a similarity-based mobility pattern-aware routing in DNTs, which uses GPS to detect the location of nodes and calculates their mobility pattern, where the more identical the mobility pattern is, the more stable their relative positions are. The mobility pattern used in Yin et al. (2009) is the intermediate node's (node r) speed direction to the destination node (node d), which is an angle (θ_{rd}).

Based on the nodes location information ((x_r, y_r) and (x_d, y_d)) and the weight controller (λ_i), a similarity degree ($f(r, d)$) is proposed to select the next forwarding node with the highest similarity degree in the source node's one-hop neighbor area

$$f(r, d) = \lambda_1 \times \frac{1}{\theta_{rd}} + \lambda_2 \times \frac{1}{\sqrt{(x_r - x_d)^2 + (y_r - y_d)^2}}. \quad (1)$$

Location-Aware Routing Protocol

Tian and Li (2010) propose a location-aware routing protocol to study the node isolation issue in DTNs. In this routing protocol, analysis of both the location information and social network structure is conducted. When the current node and the destination node are within the same

component and if the encountered node has a bigger metric than the current node, the packet is forwarded to this encountered node. Otherwise, the current node just wait next available nodes.

Furthermore, Tian and Li (2010) differentiates the operations of forwarding and replicating from existing literature. In Tian and Li (2010), a node can forward a message to an encounter node once only, and then it becomes forwarding inactive, even though it can replicate a message to other nodes without such constraint. Therefore, when the current node is in a different component to the destination node and if the current node has no previous contact with the encountered node, the packet is replicated to the encountered node. Otherwise, the packet is forwarded to the encountered node.

Location-Aided Routing Protocol

Ko and Vaidya (2000) propose location-aided routing (LAR) to show how to use the location information to reduce routing overhead by limiting the search space for a certain route. The traditional routing discovery is based on the flooding process, where source nodes broadcast route request messages. When an internode receives this request message, it compares the message destination with its own identifier. If they match, this message arrives at the final destination; otherwise, the internode needs to broadcast this message again.

LAR uses location information to reduce the number of propagated nodes where they define two concepts: the expected zone and the request zone. The expected zone is a location where a certain node has visited before. With the expected zone in mind, the forwarding process can bypass lots of useless internodes. If the source node has no idea where the expected zone is, the entire region then becomes the expected zone, and the flooding process is deployed. The request zone defines a route requesting area (flooding area), which includes the expected zone and its surrounding zones. Therefore, the size of the request zone determines the routing performance and the network overhead. One potential method to determine the size of the request zone based LAR is to find the smallest rectangle that includes

the current location and the expected zone. This expected zone is a circle area, where its center is the previous location of the destination node and its radius is the product of the time period and the node's movement speed. Therefore, the size of this request zone is subject to the average node's movement speed and the time elapsed since the last recorded known location.

Geography-Aware Active Routing Protocol

Fan et al. (2010) propose a geography-aware active data dissemination protocol in human-associated DTNs that analyzes mobile social networks from a geographic point of view. This paper uses the "community" concept from social science, which is defined as a clustering of users closely linked to each other and extends it to "geo-community" by considering the relationship of nodes on geographic related social networks. The higher the centrality of a geo-community, the better capable it is of contacting mobile users in social networks. To quantify the dynamic density of a geo-community, the following geo-centrality technique is applied as:

$$C_i(t_i) = 1 - \frac{1}{N} \sum_{k=1}^N (1 - \phi_i^k)^{t_i}, \quad (2)$$

where $C_i(t_i)$ indicates the average probability a certain user visits geo-community i at time t_i and ϕ_i^k is used to measure the steady-state probability distribution for node k in its i th geo-community. With this geo-community, the data forwarding process can be conducted by combing social and geographic information.

Key Applications

There are many applications based on delay-tolerant networks. Some typical applications can be classified as digital communication for rural areas and personal/wildlife communications.

Applications for digital communication at rural areas include:

- DakNet (Pentland et al. 2004) uses existing communications and transport infrastructure to form a delay-tolerant network, where it combines physical transportation with a wireless data transferral function to extend Internet connectivity to a central hub, such as cyberspace or a post office. DakNet does not need to relay data over a long distance, which is an advantage because it would reduce costs and save a lot of power.
- TrainNet (Zarafshan-Araki and Chin 2010) provides a low-cost and high-bandwidth link. The reason to use the train instead of other transportation methods is its fixed timetable where movements are deterministic and cover long distance. It can also carry more storage devices to store more data. The potential application of TrainNet intends to deliver a large non real-time video among any city as long as it has a train system.
- KioskNet (Seth et al. 2006) extends the idea from DakNet (Pentland et al. 2004) to have a complete system with naming, addressing, forwarding, and routing. In this system, a kiosk controller is used to provide network boot, storage, and user management functions. For those public users, they use the kiosk controller to access the executed applications. For organization users, such as government officials and NGO partners, they treat the kiosk controller as a wireless hotspot to provide a DTN function (store-and-forward) to the Internet. The main advantage of this work is the use of mechanical backhaul as ferries to carry data to the Internet gateway as they pass a kiosk. The mechanical backhaul can be cars, buses, motorcycles, or trains. During a one-way communication period (20 s to 5 mins), a 100 KB to 50 MB data can be transferred.

Applications for personal/wildlife communications are:

- Pollen network (Glance et al. 2001) borrows the idea that a plant is pollinated by insects.

For example, when an insect visits a flower to take nectar, it needs to move to a different flower as some pollen rubs off. Using the same method, when a mobile device carrier passes by an artifact, he or she can leave comments on the associated device, and it can also transfer pieces of pollen to other mobile devices. However, Pollen is not suitable for applications requiring a fast response or guaranteed delivery. Instead, it provides communication between large numbers of objects and devices, which are too expensive to be networked with the current infrastructure.

- Wireless Body Area Network (WBAN) (Qiao et al. 2011; Jovanov et al. 2005) solves on body packet routing issues in the presence of topological partitioning. Sensor nodes in WBAN are based on low-power supplied RF transceivers (Qiao et al. 2015; Cheng et al. 2014) where the signal transmission can be affected by postural body movements and clothing.
- ZebraNet (Juang et al. 2002) is designed to track wildlife in Kenya. Costumed tracking collars carried by animals are used to collect a zebra's mobility pattern and send the pattern back to a mobile base station. As the network between zebras and base stations is opportunistic, the DTN technique is used for this system. By using the DTN technique, ZebraNet stores and forwards collected mobility patterns and receives updated information from the mobile base station, which may not be available at a particular time. In addition, when base stations receive data, there may be no Internet connection, and the data has to remain at the base station.

Definitions

Data gathering is an important operation in wireless sensor networks which deals with collecting data from the sensor nodes and transmitting them to a sink (or base station) where it is further processed and available for end-user queries.

Historical Background

Wireless sensor networks (WSNs) are deployed to collect useful data from an area of interest. Data gathering is an important operation in wireless sensor networks, and it deals with collecting data from the sensor nodes. There are several aspects that should be considered when designing algorithms and protocols for data gathering:

- *Energy efficiency.* Sensor nodes are usually resource constrained, and they are equipped with batteries which often cannot be recharged or replaced. Therefore, it is important to design energy-efficient mechanisms.
- *Network elements.* There are several variations in the architecture of the network, such as the following: sensor nodes may be homogeneous or heterogeneous (e.g., they may be equipped with different types of sensing components), some of the nodes may be resource-rich devices which can serve as cluster heads or gateways; node distribution in the field; and the sink can be fix or mobile.

Sensors may be pre-programmed to measure certain parameters, or a sink may inject a request (or interest) into the network. There are few types of data delivery which trigger the data gathering protocol: periodic data delivery, query data delivery, and event-based data delivery. When the sink is responsible to inject the request or query into the network, it broadcasts a message with the requirements of the event to be monitored, such as the location, time, and threshold for the environmental measurements. Sensor nodes which receive the broadcast message and satisfy the location and time requirements, task their sensors to collect samples, and if the measurements exceed the thresholds, then they send the report to the sink.

In the periodic data delivery model, the nodes send data reports to the sink periodically, at regular time intervals, even if no specific event is present in the area. When the data delivery is event-based, the nodes only send information to the sink when an event is detected in the monitoring area. Finally, when the data delivery is query-based, the nodes in the network send information to the sink based on the requirement of the sink.

Nodes can deliver the data report to the sink directly, or using a certain infrastructure. For example, the data can be sent using a converge-cast tree rooted at the sink. One issue that can occur in this case is an *energy hole* around the sink, where the nodes close to the sink deplete their energy resources at a faster rate and eventually die, resulting in network partitioning. One option to deal with this issue is to use a certain infrastructure, such as clustering. Each cluster has a cluster head (CH) which is usually responsible for collecting and aggregating data from its cluster.

The process of finding a route to the sink can be done using a route request query (RREQ) or using a tree. In the RREQ approach, if a node has data to send to the sink, then it broadcasts a RREQ message in the network. A node that receives the RREQ message and knows a route to the sink sends back a route reply (RREP) message containing information about its route to the sink. In a tree-based approach, when the sink floods the network with an event request, a node receiving the request message will set up as its parent the node from which the message was received. In this way, a convergecast tree is formed, and assuming that the network is connected, each node has a path to the sink.

Data aggregation is an important operation in wireless sensor networks, which interleaves with data gathering. The objective is to combine data from different source nodes en route, thus eliminating redundancy and reducing the number of packets in the network, which results in energy saving. For cluster-based mechanisms, a natural approach is to have the CH perform the aggregation of the data messages in the cluster.

The clustering mechanism can be infrastructure-based or event-based. In the infrastructure-based clustering, the area is partitioned into fixed cells, and each cell has a CH. One approach is to have the node closest to the center of the cell assume the role of CH. In the event-based approach, clusters are formed on demand, only when an event is detected in the monitoring area.

Foundations

There are several design choices which affect data gathering. Next, we discuss some of the most popular architectures proposed in literature.

Homogeneous WSN with Static Sink

Direct diffusion (Intanagonwiwat et al. 2000) is an important data gathering mechanism. The sink injects a query, called interest, in the sensor network specifying the event to be monitored. This interest is diffused in the whole network. Sensor nodes located in the region of interest task their sensing components to start collecting

the information. As the interest propagates in the network, nodes record gradients which allow them to send data back to the sink. Once the sink starts receiving data, it may decide to reinforce some of the representative events. Samaras and Triantari (2016) use clustering to improve the direct diffusion mechanism. Clusters are formed with nodes that have the same interests, and the CH is selected based on the node energy level, distance to the sink, and network topology.

Heterogeneous WSN with Static Sink

In a heterogeneous network, the nodes have different sensing components or different capabilities. For example, a network may contain several resource-rich devices that can be used as cluster heads or gateways. Composite events (Gao et al. 2015) can be used to model complex events, such as fire, when more sensing attributes are needed to accurately detect the event. A composite event can be defined using one or more atomic events, where each atomic event is triggered when a single sensing value (or attribute) exceeds some threshold. In a cluster-based network model, the CHs are usually responsible for sending data to the sink. Clusters could be formed since the deployment of the network (Memon and Muntean 2012; Khan et al. 2015), or they could be triggered by the detection of an event. Event-based clustering mechanisms are proposed in the works of Aranzazu-Suescun and Cardei (2016) and Villas et al. (2012). An event-based clustering mechanism usually leads to a smaller number of clusters compared to fixed (or predefined) clustering. A smaller number of clusters detecting and reporting the events may result in energy savings. However, the process of forming the event-based clustering may add some delays in data reporting.

WSNs with Multiple Sinks

Marta and Cardei (2009) study data gathering in WSNs with multiple static sinks. The area is divided into hexagonal tiling, and sinks are located in the center of each tile. Each sink locally collects data. The study shows that the nodes closer to the sink consume more energy and are susceptible to the energy hole problem. The paper

argues that using mobile sinks can alleviate this issue.

WSNs with Mobile Sink (or Sinks)

Some of the models used for mobile sinks are random walk movement, predefined path, and controlled path. When a random walk movement of the sink is employed, the data delivery paths may become obsolete as a result of sink movement. An important concept used to deal with sink movement is the use of anchor nodes. An anchor node is usually located close to the sink, and it acts as a relay in sending data to the sink. In the articles of Tunca et al. (2015) and Hu et al. (2015), the sink selects a new anchor every time it loses its connectivity with the current anchor, as a result of moving. After a new anchor is selected, usually some information about the new anchor is flooded into the network, so that the nodes in the network revise their path to the sink. To avoid frequent updates in the network which waste energy, some authors have used multiple anchors. In this case, a new anchor is selected when the sink loses connectivity to the old anchor. Then, the process is repeated for a determined number of times before the first anchor is reselected and the process is restarted (Aranzazu-Suescun and Cardei 2017; Tian et al. 2010).

If the sink has a predefined path, then the path is usually defined by a number of polling or rendezvous points (RPs). In this case, the sink moves to each polling or rendezvous point and collects information from the closer nodes. Different approaches have been used to select the best paths to visit the RPs. Some authors Salarian et al. (2014) and Ma et al. (2013) have used different mechanisms to solve the traveling salesman problem (TSP). The TSP is NP-complete, and various approximations of the optimal tour have been proposed in literature. In the article of Ma and Yang (2008), the tour of the sink is computed using the polling points as a spanning covering tree.

In some articles, the network is divided into zones, and the path of the sink could be circular, rectangular, or linear depending on the distribution of the regions. In the work of Marta and Cardei (2009), the sinks have predefined

paths, along hexagonal regions. In the article of Abo-Zahhad et al. (2015), the sink computes its sojourn location in each region and the location of the optimal CH using the adaptive immune algorithm.

In the controlled path movement model, the sink movement depends on a specified rule in the network. One option is to trigger the sink movement when the energy of the nearby sensors decrease below some specific threshold (Khan et al. 2012; Marta and Cardei 2009). A fitness equation can be used to determine the neighboring nodes that have the higher residual energy and are closer to the sink (Patel and Bhagat 2014).

Autonomous underwater vehicles (AUVs) can be used in an underwater WSN as collectors (Javaid et al. 2015). AUVs move in the network along a predefined path gathering the information collected by gateway nodes, where the gateway nodes receive data from their neighbor nodes.

Disconnected (Partitioned) WSNs

When the network is partitioned, some mobile entities are used to collect information from different zones in the network. These mobile devices are called MULEs. One such example is using MULEs in the agricultural sensor networks (Burrell et al. 2014) where deploying a dense sensor network can be expensive. Nodes are deployed in some strategical zones, and a MULE gathers the information from each subzone. If the field is too big, then having only one MULE is not suitable because its battery can be quickly drained. The article of Jea et al. (2006) uses multiple MULEs that walk parallel in straight lines in a field. Each node in the field is assigned to a MULE such that the nodes are evenly distributed among the MULEs. A node sends data when it receives a poll message from its assigned MULE. In the work of Shah et al. (2003), the area is divided into a grid, where cells contain sensors or access points. MULEs are used to transfer data from the sensor nodes to access points. The MULEs use a random walk mobility model.

The use of unmanned aerial vehicles (UAVs) in WSNs has increased in recent years. UAVs have been used as mobile sinks and as relay nodes. In the work of Dong et al. (2014), a drone

acts as a mobile sink sending agents to the leaders of the clusters in the network. The agents collect and aggregate the information in the network and then send it to the UAV. UAVs can be used to interconnect disjoint network partitions. UAVs can travel to isolated islands of sensor nodes to collect data. If multiple UAVs are available, they can form a virtual backbone used to communicate with the sensor network (Pignaton de Freitas et al. 2010).

Key Applications

Data gathering is present in all applications of wireless sensor networks, and it should be designed according to applications' quality-of-service requirements and network characteristics.

Database-Based Spectrum Access

Haibo Zhou and Xuesen Peng
Nanjing University, Nanjing, China

Synonyms

[Cognitive radio](#); [Database](#); [Dynamic spectrum access](#); [TV white space](#)

Definition

Database-based spectrum access is a popular TV White Space (TVWS) spectrum access manner where the unlicensed users attempt to access the unused or underutilized TV bands based on a database which contains the information related to spectrum availability at a given location and time.

Historical Background

As far back as 2004, known as the first worldwide effort to utilize TVWS, IEEE 802.22 Working Group was formed to define a standard for the license-exempt devices using the TVWS spectrum which used to be occupied by TV broadcast services (Cordeiro et al. 2006). In 2010, as a milestone in TVWS exploitation, Federal Communications Commission (FCC) ruling on TVWS proposed a database-based manner to determine TVWS availability (FCC 2018). In addition, IEEE 802.11af Working Group was formed in 2010 to adopt IEEE 802.11 protocol for TV band operation. IEEE 802.11af is also called super WiFi or WhiteFi, which is designed to leverage the success of WiFi while addressing its limitations (Flores et al. 2013). Different from IEEE 802.22 which fits the outdoor scenario, IEEE 802.11af takes both the outdoor and indoor scenarios into account.

In the next few years, the database-assisted TVWS access manner attracts more and more attentions owing to the supports of government regulators, such as FCC in the US and Ofcom in the UK etc., who proposed some important memoranda in succession to advocate a database-assisted spectrum access solution (FCC 2010, 2012; Ofcom 2015). In such a solution, TVWS devices obtain the available spectrum information through querying the geolocation database, instead of performing spectrum sensing. With the evolution of TVWS exploitation, it is increasingly recognized that exploiting geolocation databases coupled with spectral sensing allows a more efficient

utilization of TVWS, especially when there exists geodatabase-unregistered Program Making and Special Event (PMSE) devices such as wireless microphones (Dionisio et al. 2014).

Foundations

TVWS is the unused or underutilized radio spectrum which used to be occupied by the licensed and protected users such as TV broadcast users and PMSE users. TVWS is also known as the VHF/UHF band locating at 470–790 MHz in Europe (Ofcom 2018; ETSI 2012) and noncontinuous 54–698 MHz in the United States (Electronic Code of Federal Regulations 2018). TVWS is now permitted to be shared by unlicensed users in their specific area without bringing interference to licensed users. Due to the abundant unlicensed spectrum resource at VHF/UHF bands and better signal penetration property for long-range wireless broadband access, TVWS exploitation has opened up a promising opportunity for massive wireless connectivity, e.g., vehicular ad hoc networks (VANET) (Flores et al. 2013). Although the database-assisted TVWS exploitation brings many benefits, the task of building up a secure and reliable database-assisted TVWS network system remains challenging (Murty et al. 2012). The TVWS network with WhiteFi Infostations (Zhou et al. 2016) to enable efficient vehicular content distribution for VANET was a feasible and efficient network system for reference, which overcame three challenges: (1) different vehicular media streaming applications of the TVWS secondary users have different quality of service (QoS) requirements, e.g., delay and throughput constraints; (2) the increasing number of the contending secondary users in the wide-range TVWS networks confront the severe medium access control (MAC) performance deterioration; and (3) vehicle mobility introduces significant dynamics to the long-range vehicular connection in TVWS. As depicted in Fig. 1, the geolocation database-assisted vehicular TVWS network was designed to be a location-aware, contention-free, and multi-polling vehicular

Database-Based Spectrum Access, Fig. 1

Geolocation database-assisted vehicular content distribution scenario

access scheme to satisfy the requirements of different vehicular media streaming applications. Like the general infrastructure-based TVWS networks, each WhiteFi Infostation first sends the required information such as its location and the transmission power to the geolocation database. The database then feeds back available vacant TV channels obtained from the primary users. Afterwards, each WhiteFi Infostation chooses the feasible channel to serve the secondary users, namely, the mobile vehicles within its transmission range.

Generally, there are two challenging issues in building up a database-assisted TVWS networks system: one is how to design the database and the other is how to price the spectrum. In the database design aspect, a robust and secure radio environment map database is required. The mathematical model applied to database design varies with application scenario. For example, the Markov decision process is suitable for the case where the spectrum lender has no knowledge of the spectrum borrower. Meanwhile, the Bayesian Stackelberg game may be a better choice when the spectrum lender has some knowledge about the spectrum borrower (Sodagari 2015). There are many rapidly changing application scenarios in TVWS networks which make the mathematical models complex and instable. As for the spectrum pricing aspect, the spectrum auction in a secondary market is a common pricing manner, where the secondary market means one in which the primary users could sell or lease idle spectrum

to many small secondary users, as opposed to the monolithic allocations in primary markets. There are many spectrum auction proposals in secondary market, such as SATYA (Kash et al. 2014), which take both the spectrum sharing and exclusive using into account, and the double-phase auction approach (Zhou et al. 2014) considering the diverse services priorities to improve the whole revenue. However, the auction-based manner brings high interaction overhead and thereby increases the communication delay. Therefore the more simple and efficient pricing strategies still need to be explored.

Key Applications

There are many potential applications for database-assisted TVWS access, such as the master-slave TVWS networks, offloading traffic to a TVWS network, TVWS serving as backhaul, rapid network deployment during emergencies, TVWS used for local TV broadcaster, etc. (RFC6953 2018).

Data-Driven Edge Computing

Siguang Chen

Nanjing University of Posts and Telecommunications, Nanjing, China

Synonyms

Edge computing; Fog computing; Local cloud; Mobile edge computing

Definition

Data-driven edge computing (also similar with local cloud and fog computing) (Lopez et al. 2015; Satyanarayanan et al. 2009; Bonomi et al. 2012; Milan et al. 2014) is a model to complement cloud computing systems by performing data processing at the edge of the network, near the source of the data. As the era of big data has arrived, billions of connected devices generating petabytes of data will demand nearby computing resources to provide real-time (or low latency) data services, edge computing decentralizes the concentration of computing resources and brings the computing closer to the devices requesting that computing power, which can improve the quality of service (QoS) and user experience significantly.

Historical Background

With the rapid and continuous deployment of enormous number of data sensing devices (such as sensors, smart meters, smart glasses, smart phones, smart vehicles, etc.), the data scale of network is showing a growth spurt. Cisco predicts

that 50 billion devices will connect to the Internet by 2020 (Evans 2011), this number will reach 500 billion by 2025 (Camhi 2015). By 2019, the data produced by people, machines, and things will reach 500 zettabytes (Cisco 2014). The large-scale data often accompanied by the great burden of data processing, collection, and storage. The traditional architectures of wireless sensor network (WSN), ad hoc, and Internet of Things (IoTs) cannot satisfy the requirement of efficient data processing. How to relieve the processing pressure of big data and improve the QoS becomes a great challenge.

Edge computing is usually deployed at local region and used to compensate drawbacks of cloud computing, which can utilize the computation capabilities of edge (local) devices effectively. The preprocessing operation of edge device can alleviate the data processing burden of cloud node and reduce the communication overhead of network significantly (Chen et al. 2018). Overall, the employing of fog computing can reduce computation latency, bandwidth, and energy consumptions significantly. For the sake of effectively using the edge device's computation and storage resources, improving the QoS and user experience, numerous edge computing-based schemes are developed to achieve such goal.

Latency is an important performance metric for user experience. The work of Rimal et al. (2016) investigated performance gains of centralized cloud and mobile edge computing (MEC) enabled integrated fiber-wireless (FiWi) access networks, which shows the offload packet delay can be reduced without affecting network performance of broadband access traffic. Varghese et al. (2017) highlighted the feasibility and the benefits in improving the QoS and experience by using fog computing. The experimental results demonstrate that the average response time for a user is improved by 20% when using the edge of the network in comparison to using a cloud-only model. Meanwhile, the volume of traffic between the edge and the cloud server is reduced by over 90% for the use case.

Bandwidth consumption is an important performance metric for QoS. From latency

perspective, low bandwidth consumption can reduce the network congestion and then reduce transmission time, especially for large data (e.g., video stream, etc.). Edge computing urges the video stream which don't need to route to the central cloud, it avoids a great amount of network bandwidth consumption due to the nature of video stream, and also avoids the problem of network congestion caused by the video stream uploading. The work of Mehta et al. (2016) studied the benefit of introducing additional data centers closer to the network edge for the optimal application placement. The study shows that the cost savings for such operation can go up to 67% for the bandwidth-hungry applications. The similar research results indicate that backhaul savings can go up to 22% by exploiting the proactive caching scheme (Bastug et al. 2014).

Energy consumption is an important performance metric for network efficiency. Battery is the most precious resource for devices at the edge of the network; the research work shows that the energy consumption in the device can be reduced by up to 42% through offloading to edge servers compared to cloud offloading (Gao et al. 2015). Zhang et al. (2016) developed an energy-efficient computation offloading (EECO) mechanisms for MEC in 5G heterogeneous networks. The proposed mechanism jointly optimizes offloading and radio resource allocation to obtain the minimal energy consumption under the latency constraints.

For detailed information on the background and state of the art of edge computing, please read the review works of Wang et al. (2017) and Ni et al. (2018).

Foundations

The following figure shows a typical data-driven edge-cloud computing model for Internet of Things (IoT) systems.

As shown in Fig. 1, a hierarchical IoT computing system consisting of one remote cloud server, several edge nodes, and a number of IoT devices is constructed. Each IoT device with a volume of data is connected to the nearby edge node

Data-Driven Edge Computing, Fig. 1 Data-driven edge-cloud computing model

through the wireless access point. The edge node receives the data processing requests uploaded by the nearby devices and will return the results to the terminal devices after these requests are processed. The edge node can provide timely data processing services for time-sensitive applications. Meanwhile, when the edge node is overloaded, it can offload the partial computation tasks to the cloud server for improving the user experience and extending the finite computation and storage capabilities of edge node. This hybrid edge-cloud computing paradigm can make full use of the advantages of both edge and cloud computing modes and meet the data processing requirements of big data scenario.

Key Applications

The advantages of edge computing urge that can be applied in various fields, such as dynamic content delivery, video analytics, IoTs, vehicular networks, big data analytics, etc.

1. Dynamic content delivery

In the edge computing paradigm, not only data should be cached at the edge server but also it can perform operations on the data. Caching and processing at the edge server can

provide dynamic content delivery based on the network information (such as network load, network status, etc.) and user's context-aware information (Zhu et al. 2013). One typical application is online shopping services for the frequent changes of shopping cart. Edge-based dynamic content delivery improves the quality of experience (QoE) for approaching to end users effectively.

2. Video analytics

With the continuous increasing of video monitoring devices and network cameras, the video analytics become an emerging technology. The use of edge computing paradigm allows the video analysis at any edge devices and gets the result much faster compared with traditional cloud computing. The user requests of data analysis perform at local devices which avoid numerous redundant video streams transport through the core network to cloud server. Traditional cloud computing is no longer suitable for video analytics application due to the high latency of long distance transmission and privacy concerns.

3. Internet of Things

The application fields of edge computing paradigm in IoTs mainly include smart health-

care, smart grid, smart home, smart transportation, etc. In healthcare applications, real-time processing and emergent event response are very important for stroke patients and sudden cardiac death. Edge computing paradigm can definitely shorten the time of first aid and improve the success rate in rescuing patients (Ni et al. 2018). Similarly, edge computing can provide efficient energy consumption collection scheme for smart grid, offer low latency, localized, and plug and play services for smart home (Wang et al. 2017), and improve traffic jam and safety for vehicles and pedestrian.

4. Vehicular networks

Nowadays, a vehicle can communicate with other vehicles (V2V), surrounding infrastructure (V2I), the Internet (V2N), roadside pedestrian (V2P), and a back-end cloud server (Liu et al. 2016); it means that the vehicle can communicate with everything (V2X). V2X can achieve a series of new applications, such as automated overtake, autonomous driving, cooperative collision avoidance, bird's eye view, traffic prediction, and smart parking (Wan et al. 2016; Han et al. 2016; Liu et al. 2017). MEC can reduce the transmission latency and cost of the computation offloading for the close proximity to the mobile vehicular terminals.

5. Big data analytics

With the rapid increasing of data scale, big data analytics becomes a huge challenge for traditional cloud-based network, since the data collection from the terminal devices are transmitted to the remote cloud server for big data analytics. Edge computing can manage and use the local computing and storage resources, and is a promising choice to handle big data for which can reduce the bandwidth consumption and improve response time.

Data-Driven Mobile Social Networks

Fuliang Li
Northeastern University, Shenyang, China

Synonyms

Mobile big data; Mobile social network

Definitions

Mobile social networks (MSNs) combine the social networks with the mobile communication networks. In MSN, users with similar interests communicate with one another through their mobile devices. Data-driven MSNs take full advantages of mobile big data analysis to improve the design and optimize the performance of MSNs.

Historical Background

Online social networks (OSNs, e.g., Ins, Facebook, and Twitter) provide a platform for the people with the similar interests and background and to communicate with one another (Schneider et al. 2009). Most OSNs are the web-based applications. Some studies have confirmed that there are positive psychological outcomes from OSNs compared with the traditional offline social networks (Oh et al. 2014). However, with the development of wireless access technology, as well as the wide popularity of mobile devices, mobile users increase sharply. As a result, the traditional PC end users are replaced by the mobile end users gradually in OSNs. To provide better services for mobile users, mobile social networks (MSNs) have emerged, which leverage the characteristics of social networks in combination with mobile communication networks (Hu et al. 2015). On one hand, with the aid of the social measurements in social networks, the routing mechanism in mobile communication networks can be optimized, and thus the quality of experience is improved as well. On the other hand, social networks can exploit the ubiquitous accessibility of mobile communication networks to realize real-time interaction even without connections to the Internet. In our daily life, many MSN applications have been developed based on the location and sensing, such as Geo-Life (Zheng et al. 2009), Foursquare (Foursquare 2018), and Micro-blog (Gaonkar et al. 2008), etc.

Unlike traditional OSNs, MSNs fully utilizes the characteristics of mobile devices, such as portability and multiple sensing capabilities (Mao et al. 2017). On one hand, owing to the portability, mobile users can access any social platforms anywhere at any time. On the other hand, mobile devices integrate a variety of sensors, such as light sensor, accelerator sensor, gyroscope, temperature sensor, blood pressure sensor and heart rate sensor, etc. The multiple sensing capabilities strengthen the relations between MSNs and mobile users. There are three typical architectures of MSNs listed as follows.

- *Centralized MSN.* It follows the C/S mode, and all data are stored in the centralized servers. Communications among the mobile devices are based on the Internet through wireless access technologies, such as 4G and Wi-Fi, etc.
- *Distributed MSN.* In this architecture, none of centralized servers are utilized. Mobile users directly communicate with one another based on the device-to-device (D2D) communication technologies, such as Bluetooth (Bluetooth 2018) and Wi-Fi Direct (WFD 2016), etc.
- *Hybrid MSN.* This is a hybrid architecture of the above two cases. It supports the infrastructure-based communications (i.e., centralized MSN), as well as the infrastructure-less communications (i.e., distributed MSN). The hybrid MSN is a flexible solution, and it depends on the practical MSN-based applications

The social attribute is a typical characteristic of MSNs. To measure the social attributes, social behavior analysis is introduced (Hu et al. 2015). Social behavior can be derived from the social relationship (Li and Chen 2009) and the social influence (Peng et al. 2017). Additionally, the capability of context awareness of users is a major advantage of MSNs (Mao et al. 2017). With the help of the embedded sensors in mobile devices, MSNs can capture the contextual information, for example, the location information without user intervention. Based on the contextual information, the functions of MSN applications can be extended and diversified (Araniti et al. 2017; Yu et al. 2017). However, how to protect the user privacy in MSNs becomes a challenging issue. Li et al. (2018) proposed a novel attack that utilizes the information of users' location to infer the demographic attributes. And then they presented a privacy control approach called SmartMask to defense the attack. Wang et al. (2018) proposed a two-hop feedback-based dynamic trust framework to recognize the selfish and malicious nodes in opportunistic MSNs, which could defense the conspiracy attacks

effectively. To ensure the security and efficiency of content caching in fog computing enabled MSNs, Su et al. (2018) proposed a secure content caching schema following the idea of disaster backup.

In MSNs, researchers and developers require to acquire lots of data from mobile devices. As mobile traffic will increase sevenfold between 2016 and 2021 (Cis 2017), mobile data already have the typical characteristics of big data, such as large volume and economic value (Hu et al. 2014). By analyzing the mobile data, some valuable information could be obtained to improve the design and optimize the performance of MSNs. Whereas how to reasonably store, manage, deliver, and control these mobile big data has become a challenging issue (Su et al. 2016), which promotes the evolution of data-driven MSNs.

In fact, the data-driven is an idea, which can be implemented by some specific approaches, such as data mining and machine learning, etc. Du et al. (2011) used the standard Markov model and the semi-Markov model to predict the user mobility. In opportunistic networks, the connectivity of nodes is discontinuous, and the mobility of nodes is driven by human sociality. To improve the communication success rate, a sociality-driven communication method was introduced (Societevole et al. 2015), which could reflect the social behaviors of nodes and discover available relays for message forwarding. It is effective to adopt the data-driven thought to characterize the user mobility in a wide range of mobile computing applications. Yuan et al. (2016) proposed a model based on data analysis to identify unlicensed taxis. The model firstly screened out a coarse-grained suspected unlicensed taxi candidate list. Then, the results were used to get a fine-grained list of suspected unlicensed taxis based on machine learning.

There are many studies on optimizing MSNs based on the data-driven thought. Zhang et al. (2018) conducted traffic prediction based on the data gathered from WeChat Moments. They also discussed how to develop new MSN applications with the help of the mobile big data.

Wu et al. (2017) collected some user information from 17000 mobile devices. Results revealed that the social relationship has a great impact on tweet click behaviors. In addition, they also presented a cluster-based Latent Bias Model for data-driven learning-based prefetching prediction in MSNs. Data-driven modeling should be conducted based on big data to ensure the correctness and the effectiveness. Wang et al. (2017) pointed out that limited data analysis caused by small scale of dataset or single-dimensional feature may restrict the applications in practice severely. And they analyzed the behaviors of 30 million users from the platform of Xender for device-to-device content sharing in MSNs. Song et al. (2015) proposed a model based on Bayes' rule to predict the user locations in social networks by social influence from the perspectives of temporal and spatial, respectively. They found that, in location-based social networks, the social influence plays an important role in modeling user mobility through analyzing the check-in movement behaviors of users. Shi et al. (2016) investigated the impacts of space and place on social networks using mobile phone data. They confirmed the distance decay effects in social networks and found that individuals interaction is a more important factor than spatial proximity.

Given above, the data-driven thought can take full advantages of mobile big data analysis to promote the development of MSNs. Through data-driven modeling, the existing designs of MSNs such as routing and data sharing could be improved and optimized. Therefore, data-driven MSN has become a promising field in the current research on MSNs.

Key Applications

Data-driven MSNs take full advantages of mobile big data analysis to improve the design and optimize the performance of MSNs, which could act the basis for offloading computing and edge computing.

Data-Driven Network Control

An Xie and Xiaoliang Wang

Department of Computer Science and Technology, Nanjing University, Nanjing, Jiangsu Province, China

Background

Traditionally, network control is usually optimized for better experience of applications with the goal of avoiding congestion or reducing flow completion time in data center. To this end, enormous amount of researches have focused on adjusting parameters of certain transmission protocols, such as TCP, DCTCP, D2TCP, etc. These works can be summarized as “optimizing applications by adjusting network control.”

With the emerging of big data, tremendous amount of data is generated in end devices or by data applications in data center. As a result, how to leverage the benefit of this huge amount of data to better control the network has attracted research communities’ attention. The new paradigm, referred to as “Data-Driven network Control,” aims at improving network performance by leveraging user/applications-generated data. Compared to the traditional “optimizing applications by adjusting network control,” data-driven network control can be identified in the opposite direction, i.e., “optimization network control by data of applications.”

In the following, we will first introduce some basic concepts and mechanism of data-driven network control. Then we will compare the traditional model-based control with data-driven control to highlight unique properties of data-driven control. At last, some preliminary applications are given to show potential benefits of data-driven network control.

Data-Driven Network Control

The main idea of data-driven network control is to exploit large volumes of network data to

optimize network performance. Most network control mechanisms nowadays use only local data of a single flow. In contrast, data-driven network control uses data from multiple flows or even the network to make better control decisions.

The Opportunity of Using Big Data for Network Control

Tremendous network devices and users are generating more data than ever before. For example, according to the report of IBM, 2.5 quintillion bytes of data are created everyday (Wu et al. 2014). Big data is usually characterized by five V's: (1) volume, i.e., the size of data is huge; (2) velocity, i.e., the data production rate is high; (3) variety, i.e., the type of data is various; (4) veracity, i.e., the quality of data is high; (5) value, i.e., the data is in general useful. It is notable that the produced data sets are so large and complex that traditional methods are inadequate to accurately model and analyze them. Therefore, people may refer to new technologies such as data mining and machine learning.

Definition of Data-Driven Network Control

We borrow the definition from (Jiang et al. 2017) as follows. Data-driven network is a paradigm for designing the control plane of network protocols. Data-driven network contains two components: the client-side instrumentation and the controller. The client-side instrumentation is responsible for measuring client-perceived quality and applying decisions made by the controller while the controller is responsible for aggregating measurements and making control decisions.

Mechanism of Data-Driven Network Control

We introduce the mechanism of data-driven network control on the three-layer architecture from (Yao et al. 2016) which contains infrastructure layer, control layer, and application layer.

- *The infrastructure layer.* This is where the client-side instrumentation resides. It may contain various devices, such as switches,

access points, and smart phones. Devices in the infrastructure layer usually implement protocols through which the control layer can fetch statistics or logs. For example, the OpenFlow protocol in SDN allows controller to query flow statistics. Devices in the infrastructure layer also accept orders from the control layer to alter network configuration.

- *The control layer.* The controller is in this layer. This layer resides between the infrastructure layer and the application layer. The main responsibility of the control layer is to analyze data collected from the infrastructure layer. As stated above, in general, both the number of devices and the amount of data are huge. Therefore, data-driven approaches like machine learning and data mining are advantageous over the model based approaches.
- *The application layer* contains user applications and it resides on top of the control layer. Applications obtain models generated by the control layer. In conjunction with the network management protocols such as SNMP or SDN on the control layer, applications can maximize their performance by dynamically changing network parameters.

Model-Based Control Versus Data-Driven Control

To design a control system from data, there are mainly two approaches, i.e., the model-based approach and the data-driven approach. The model-based approach first derives a model from the data after which a controller is computed based on the model. In contrast, the data-driven approach directly derives the controller from the data.

Model-Based Control (MBC)

The model-based control requires that the parameters be calibrated using collected data that minimizing the model reference criterion or satisfying some user-defined requirements. The derived model either reflects or approximates the true

system. According to (Murray 2010), the model-based design has the following advantages:

- Model-based design provides a common design environment, which facilitates general communication, data analysis, and system verification between various groups.
- Engineers can locate and correct errors early in system design, when the time and financial impact of system modification are minimized.
- Design reuse, for upgrades and for derivative systems with expanded capabilities, is facilitated.

The main problems of this approach are that the performance strongly depends on the modeling technique and is limited by the modeling errors.

Data-Driven Control (DDC)

Sometimes it not possible and feasible to get the accurate model of objects. Reasons are twofold. First, it may be difficult to get the accurate model of every object. For example, in Internet of Things (IoT), there are a large number of devices. Second, it may be too difficult to model even one object. This is because that many industry processes, aerospace systems, transportation systems, power grid systems, etc., are becoming more and more complex. Fortunately, in many cases, collecting data is relatively easy thanks to the development of information technology and the decrease in the price of storage media. Moreover, it may be the only way we know about objects in IoT.

Data-driven control aims at making full use of those data, either collected online or offline. It directly derives the control system from the data instead of first modeling the plant and then designing the controller using the plant model. At the same time, properties such as stability, convergence, and robustness can be guaranteed under certain assumptions. The main advantages of data-driven control are summarized as follows (Hou and Wang 2013):

- The controller in DDC approaches does not explicitly include any parts or the whole of the plant model. For this reason, it has overcome the dependence on the plant model for the design of control systems.
- The stability and convergence conclusions of DDC approaches do not depend upon the accuracy of the model, excepting the DDC control methods implicitly using the system dynamics and structure information, such as direct adaptive control, subspace predictive control, which is the main stumbling block for the applications of the MBC theory.
- The most outstanding point of DDC approaches is that the twinborn problem of un-modeled dynamics and robustness in traditional MBC theory do not exist under DDC framework.

In the following section, we review some illustrative applications based on data-driven network control paradigm.

Applications

Better CDN Selection

The observed video quality delivered by individual CDNs can vary substantially across clients and time. As the video player has only a few seconds to do the buffering, decisions need to be made quickly to let the buffer not drain out. C3 (Ganjam et al. 2015) is one data-driven approach of dynamic CDN selection by exploiting quality measurements of other video sessions. C3 is composed of two layers, i.e., a global controller and a client side sensing/actuation layers. The controller uses real-time measurements of sensing/actuation layer. These measurements are used by the controller to create a model of expected performance and in turn, this model is used by the controller to decide suitable parameters such as CDN and bitrate for clients. The decisions are executed on the sensing/actuation layers. C3 has been operational for 8 years, and has improved the video quality significantly.

Adaptive Bitrate Selection

Adaptive bitrate selection is critical to ensure good Quality of Experience (QoE) for Internet video. To meet the increasing stringent QoE demand of users, video players need intelligent bitrate selection and adaptation algorithms. To this end, accurate throughput prediction plays a vital role in designing the two algorithms. CS2P (Sun et al. 2016) analyzes throughput characteristics in a dataset with 20M+ sessions from one of the biggest video providers in China, iQIYI. CS2P reveals that sessions sharing similar key features such as ISP and region have similar initial throughput values and dynamic patterns. Besides, a natural stateful behavior exists in throughput variability within a given session.

Based on the findings, CS2P develops an offline clustering based prediction model using observed throughput from past video sessions. The model clusters sessions that are likely to exhibit similar throughput patterns. CS2P determines the initial throughput for each cluster by the median throughput. Moreover, CS2P learns a Hidden-Markov-Model (HMM) for each cluster to model the stateful evolution of intrasession throughput. The two models are then plugged into the video player and determine the initial bitrate and midstream bitrate adaption online. CS2P achieves 3.2% improvement on overall QoE and 10.9% higher average bitrate over state-of-art Model Predictive Control (MPC) approach.

Data-Driven Pattern Prediction

Zhuzhong Qian

State Key Laboratory for Novel Software Technology, Nanjing University, Nanjing, China

Synonyms

[Data Mining](#); [Data Analytics](#)

Definition

Data-driven pattern prediction is the process of using large volume of related historical data to extract the inner patterns of some observed objects on their behaviors or some phenomena, and then using extracted patterns to make accurate prediction rapidly.

Key Application

- Guiding keyword bidding based on the patterns of user clicks from web logs.
- Guiding traffic evacuation based on the patterns of rush hours in a city.
- Guiding resource management based on the patterns of resource demands in a cluster.

Background of Data-Driven Pattern Prediction

With the rapid growth of the Internet, there is a huge amount of data accumulated in human's activities. For example, within the Internet minute in 2013 (Lena long 2013), there are tens of thousands of application downloads, millions of search queries, and tens of millions of photo views. As a result, hundreds of thousands of gigabytes are transferred globally through IP packets over the network within an Internet Minute. Apart from those network activities, millions of cameras have already deployed around the world (Zhang et al. 2017), which would also generate large volume of data for surveillance and business intelligence.

Such large volume of data, also well known as big data (Big Data 2016), can be used for predictive analytics, user behavior analytics, or certain other advanced data analytics methods by extracting valuable information from data. The new paradigm, referred to as "data-driven analysis," aims at digging valuable information from the big data to help improve the performance of the network, enhance the surveillance, spur the business intelligence, etc. Note that there are many inner patterns existing within big data. For example, as shown in Fig. 1, the population of Manhattan changes with patterns. The data is collected from the Metropolitan Transportation Authority's turnstile database (Turnstile Data of Metropolitan Transportation Authority 2018) (nearly 10GB data) and Steven Romalewski's MTA subway data (Mta Subway Data 2018). Although the population changes hour by hour, there are periodical waves between two different days. This is because the tidal routine of people occurs day by day. Therefore, if we can extract the patterns and make prediction based on the changes of population from the big data of subway, we have more opportunities to improve the public transportation or solve other related problems.

Apart from the public transportation, we can extract the valuable patterns from data and make prediction for wide range of scenarios. For exam-

ple, we can use the logs from websites/sessions to capture the browsing patterns of users, guiding better user experience. We can also use the resource demands from various applications during their executions to guide the efficient resource management within clouds, edges, and so on.

Data-Driven Pattern Prediction

Here, the process of extracting valuable information from data is called "data-driven." Due to the existence and value of inner patterns inside big data, extracting patterns and making prediction from big data is urgent for data analysts. But, how to extract the patterns from big data is a big challenge. Traditionally, the concept of extracting patterns from data is similar with data mining. However, digging valuable information from large volume of data is far from simple data mining. This is because the volume of data and the velocity of data generation limit the efficient use of simple algorithms from data mining. Therefore, we summarize the key indicators of data-driven pattern prediction:

- **Accuracy.** The main indicator of a prediction model is its accuracy. It is awful to imagine that making prediction is just like guessing randomly. The accuracy of models would no doubt influence the use of patterns and leading to misleading behaviors and incurring great loss. Thus, pattern prediction without accuracy is useless to practical applications.
- **Efficiency.** Due to the large volume of generated data, if the models cannot treat data rapidly, the prediction would lose its timelessness. For example, if an application wants to decide how to conduct resource management for submitted requests, then it is unsuitable to queue requests for long time to conduct online prediction. We should mention here that the rapid response of prediction is the requirement for online scenario, not the offline data training progress. This is because it is worthy spending adequate time on offline training in order to have quick and accurate response for those online demands.

Data-Driven Pattern Prediction, Fig. 1 The population of Manhattan, hour by hour (2018). (a) Monday, 8:00. (b) Monday, 12:00. (c) Monday, 16:00. (d) Monday, 20:00. (e) Tuesday, 8:00. (f) Tuesday, 12:00. (g) Tuesday, 16:00. (h) Tuesday, 20:00

- **Scalability.** Under realistic scenarios, the volume of datasets and the dimension of features are extremely high. How to design an algorithm with high scalability to extract the patterns from big data is important. This is because it can help us find out the best suitable scenario to use such of these algorithms.

Fortunately, we can use the techniques from data mining as a guide to help design data-driven pattern prediction algorithms. Most of the techniques from machine learning, statistics, and database can be used to data-driven pattern prediction through some revisions. For example, we can use deep learning, reinforcement learning, and so on to capture the patterns for realistic applications. And at the same time, we should pay more attention on how to apply those approaches with high accuracy, efficiency, and scalability. Basically, data-driven pattern prediction has following steps:

- **Data Preprocessing.** The main idea behind for data preprocessing is to form the raw data into regular structures and at the same time, to treat the missing data for use. This is because the raw data collected from real world may have redundant information or missing fields.
- **Pattern Extraction.** This step focuses on extracting valuable patterns or conclusions from preprocessed datasets by using the techniques from machine learning, statistics, and database. We should mention here that the efficiency and accuracy are of great concern. This is because misleading conclusions or delayed news have less value for realistic scenarios.
- **Prediction based on Patterns.** This step mainly uses extracted patterns or conclusions from data to guide improving performance or solving meaningful problems, which is the key step to show the value of data.

Definition

Recently, the strict definition of data-driven QoE measurement has not been given. The International Telecommunication Union (ITU-T) has defined the QoE concept as *the entire thing of availability of services subjectively perceived by end users*. The definition of QoE by the European Qualinet is the degree of satisfaction or annoyance of the end users of services because the utility and/or the expectations regarding services are based on end-user attitudes and current service situations (He et al. 2018). Furthermore, data-driven QoE measurement can be defined from the perspective of objective-based or subjective-based metrics. Generally speaking, data-driven QoE measurement is the end-user-centric metric that is used to measure end-user acceptance or satisfaction of data services or applications. In addition, data-driven QoE measurement is the extended version of data-driven QoS measurement used for judging delay-sensitive data from the end-user perspective (Wang et al. 2018). In summary, the common understanding of data-driven QoE

measurement is as follows: data-driven QoE measurement is a new measurement for data services which is based on the interactions between end users and services.

Historical Background

The data-driven QoE concept is a well-known measurement mechanism for determining the overall perception of the data-driven QoS, i.e., the evaluation of data-driven QoS as experienced by end users. Recently, many data-driven QoS-based methods have been developed to optimize the efficiency and performance of the environment, as proposed by the authors in Fang et al. (2016). Even though the parameters of data-driven QoS offer good objective measurement criteria, they cannot directly determine the quality of end-user perceptions. Therefore, both academic and industry researchers have shifted their attention from data-driven QoS parameters like jitter, throughput, packet loss, and delay to the concept of data-driven QoE. Data-driven QoE, in contrast, can refer to both the performance and efficiency of services as measured by data-driven QoS, as well as the subjective opinions of end users. Therefore, data-driven QoE is more suitable with respect to end users in a form of measurement than is data-driven QoS.

In fact, data-driven QoE analysis is paid close attention to the data-driven QoS metrics, i.e., bitrate, rebuffering, and delay. Data-driven QoE analysis models have appeared of late due to availability of large-scale data accompanied by the promising popularity of traffic and/or streaming around the Internet. In particular, video streaming/traffic has the availability of large-scale data in order to analyze QoE around the Internet (Wang et al. 2019). Later on, some extensions to the data-driven QoE analysis model have been studied. QoE analysis model with linear regression and correlation has been proposed in Du et al. (2018). The Kendall correlation coefficient can be selected to calculate the correlations between each metrics of data-driven QoS and data-driven QoE. Then the collection of information can help to get a

deeper understanding of the relationship between data-driven QoS and QoE via refining how the intellectual of uncertainty of the data-driven QoE metrics increases a certain data-driven QoS metric. Finally, linear regression-based curve fitting is the application to the data-driven pairs of QoS-QoE. By observing the data-driven QoS-QoE curves, the relationship is not linear in the whole environments. Additionally, a decision tree-based QoE prediction model is developed in Wang et al. (2016) to eliminate defects of correlation and linear regression analysis.

Also, data-driven QoE management has been studied. For example, a data-driven management architecture for personalized QoE is proposed to assess QoE from user perspective involving the subjective characteristics of end users (Wang et al. 2016). Then, a reinforcement learning-based method has been used for QoE-based spectrum handoff management (Xu et al. 2018). Data-aware QoE-QoS management method based on principle component analysis proposed to balance QoE-QoS management (Usman et al. 2018).

Lastly, several data-driven QoE manners, e.g., evaluation, and visualization have been proposed to enable data-driven QoE optimization in Jiang et al. (2017). Content providers can get amazing profits from data-driven platform via transferring strategies of load balance based on QoE server statement visualization and monitoring (Wang et al. 2016).

Key Applications

The common understanding of data-driven QoE is a novel measurement technique for applications or services and is confirmed based on the quality of whole environments and the experience of end users. Data-driven QoE measurement has been applied to a variety of scenarios.

Video streaming The flexibility is used to stream interesting content from CDNs and/or multiple servers in different bitrates by VoD offers that already put real-time visibility into video quality by the instrumentation of client (Zhang et al. 2017). In contrast to the

traditional methods, current work has displayed the operation on a single-session basis; data-driven methods for CDN selection and bitrate can enhance the quality of video (e.g., 50 percent less buffer in time) (Jiang et al. 2016a). Similarly, the overlay path between edge servers and sources is the dependence of live streaming QoE (e.g., ESPN, twitch.tv). Once these overlay paths are the choices to tackle traffic and the fluctuation of quality dynamically, there could be development space for enhancement. Existing works have been introduced to leverage video quality in the following.

- **Design of media player buffer:** The design of media player buffer is crucial adjective because the event of rebuffering has a vital impact on QoE of end users. The size of buffer will affect the delay and time of rebuffering. The delay will be longer since more and more data can be downloaded before the player plays if the buffer size is large. During the playing state, vice versa, however, fewer events of rebuffering can happen. Additionally, He et al. (2018) has been shown that most of the downloaded data in the buffer is not useful due to many end users quitting before the completions of video.
- **Congestion control:** Conventional TCP protocol applied to video traffic can result in long delay owing to the following reasons: (1) considering the TCP protocol, a lost packet will be retransferred when it is received successfully, leading to a long delay and get a poor QoE; (2) the additive increase multiplicative decrease (AIMD) algorithm results in fluctuated throughput around the time, which will increase the delay and result in end-user dissatisfaction; and (3) the congestion control is QoS-based, whereas the video is QoE-based. Sterca et al. (2016) proposed the Media-TCP to design a mechanism of congestion control video-friendly for the TCP protocol, optimizing the congestion window size, which maximize the long-term QoE. The distortion delay and influence deadline of

each packet are considered to offer different services or applications for different packet classes. Media-TCP is shown to improve the PSNR around methods of conventional TCP congestion control. Unfortunately, Wang et al. (2017b) proposed Media-TCP, which is still QoS-based, a MOS-based congestion control for multimedia transmission. The value of MOS is predicted in real-time manner via the Lync system of Microsoft on the basis of quantitative measurements (i.e., packet loss, bit errors, packet delay, and jitter). Then QoE-based adaption of congestion window is formulated as a partially observable Markov decision process (POMDP) and is solved by the algorithm of online learning. Another method is the use of protocol such as video-friendly application, Dynamic Adaptive Streaming over HTTP (DASH), mitigating the delay problem in video transmission and not changing the TCP protocol.

Internet telephony Recently, applications of VoIP (i.e., Skype and Hangouts) are useful for managed relays, optimizing performances between network clients. In contrast to any cast-based relay selection, recent work has been shown that a data-driven algorithm of relay selection can reduce the number of poor-quality calls (i.e., 42 percent fewer calls with over 1.2 percent packet loss) (Canbaz et al. 2017). Thereby, the satisfaction of QoE can be given by the proposed data-driven algorithm in the Internet telephony.

File sharing The flexibility of file-sharing applications (e.g., Dropbox) allows each client to catch files from a chosen data center or server. We can enhance the QoE for these services or applications potentially by the use of data-driven methods to predict the throughput between a server and client (Chen et al. 2015).

Web services With the applications of social network, we will attempt to optimize server selection. The goal is to get information of the co-

location. Recent work has shown that optimal caching and server selection can reduce query time of Facebook to 50 percent (Du et al. 2018). Online services (e.g., search) can also benefit from data-driven techniques. For example, compared to anycast, edge sever selection of data can reduce search latency by 60 percent serving $2\times$ more queries. Therefore, using data-driven technology in Web services is beneficial to the reduction of latency and, furthermore, brings better QoE performance.

[Big data computing](#); [Data-driven scheduling](#); [Distributed computing](#)

Definition

Data-driven resource allocation is a methodology that resource allocation in computer systems is mainly according to data storage and processing. In data-driven resource allocation, resources need to be allocated for supporting the data-flow between storage and processors. Since big data application usually needs data-intensive computing, it is very important to allocate resource for massive data storage and transfer.

Historical Background

Resource allocation is an important problem in modern computing systems (Dong et al.

2008). When a task is executed in a general computing system, it is necessary to allocate enough resources for it to normally work. Usually, resources in computing systems include memory space, storage space, processor time, network bandwidth, and so on. For a multitasking computing system, it needs a dedicated resource allocation strategy to finish tasks with limited resources.

There are many resource allocation strategies in different computing systems. In early multitasking computers, the operating systems allocate fixed resources for different tasks (Vasudevan et al. 2015). For example, in the oldest round-robin scheduling, the task scheduler will assign a fixed number of processor time slices to each task (Hahne 1991). However, since required resources of tasks are different, fixed resource allocation strategy is equitable but not efficient.

Another methodology of resource allocation is the on-demand strategy that resources are allocated to tasks according to their requests (Albonesi 1999). In memory space allocation, operating systems usually assign required memory of each task. Thus, the maximum number of executing tasks in a computing system is usually limited by the total memory space (Avisar et al. 2002).

In a distributed computing system, the resource allocation problem becomes more complex because of the communication between distributed servers (Kurose and Simha 1989). Usually, since most distributed computing systems are built on commercial hardware, the communication bandwidth is more limited than processor time and memory space. The allocation strategy of network resources affects the performance of the total distributed systems (Li et al. 2014).

Therefore, in network bandwidth allocation for distributed systems, it needs to understand the traffic of each task and then allocate the appropriate bandwidth to tasks. Since most network traffic between servers depends on the data-flows of each task, a data-driven network resource allocation plays an important role in distributed computing systems (Li et al. 2015b).

Data-intensive computing such as big data processing and multimedia computing becomes more and more important in recent years (Wu et al. 2016). For data-intensive computing tasks, the storage resources are more important than processor resources. Due to slow storage hardware, high-speed memory allocation for data-intensive tasks is much harder than compute-intensive tasks (Li et al. 2015a). Allocating resource for data-intensive tasks becomes another important area of data-driven resource allocation.

Data-driven resource allocation is also very important for stream computing that processes large data streams from real-time sources. Since data-flows of different stream computing tasks are usually different, it needs a suitable resource allocation paradigm to allocate resources accordingly and to predict data-flow of each task.

Researchers begin to apply data-driven resource allocation paradigm in some new problems. For example, in training deep learning models, a large amount of data will be transferred from storage devices or memory to some specific computing devices such as graphics processing units (GPUs) or application-specific integrated circuit (ASIC) chips. Therefore, data-driven resource allocation strategies are applied to optimize the resource allocation in training varying deep learning models.

Key Applications

According to the importances discussed above, data-driven resource allocation can be applied in many applications such as big data computing, cloud computing, edge computing, deep learning, and Internet-of-Things (IoT).

1. Big data computing

In big data computing, data-driven resource allocation plays a very important role for the data processing efficiency. For example, in traditional MapReduce computing model, the resource

allocation needs to follow the data-flows due to the heavy traffic and IO from mapping to reducing phase.

2. Cloud computing

Cloud offers computing resources for different applications with the pay-as-you-go model. For cloud providers, it is still a difficult problem to allocate resources to different applications with quality-of-service (QoS) guarantees. There are more and more data-intensive applications being deployed on cloud platforms in recent years. Due to the high concentration of the IO model applied in cloud computing, efficient data-driven resource allocations are essential to QoS-guaranteed cloud services.

3. Edge computing

Edge computing can off-load computing or storage loads from cloud servers to the edge. Usually, due to the high mobility of edge devices, it is very important to allocate resources according to the mobile data-flows between edge nodes and devices. Meanwhile, it also needs a data-driven resource allocation for different services deployed in the edge since most edge devices or nodes have limited storage space and computational capacity.

4. Deep learning

In deep learning tasks, especially in training deep learning models, massive datasets are transferred from storage devices to the learning networks. Since the learning networks become more and more complex, it needs distributed learning systems to reduce the training time. Meanwhile, the intermediate data are shuffled between different computational devices in training tasks. Therefore, with the rapid development of deep learning technologies, it is necessary to work out deep learning-oriented data-driven resource allocation strategies according to the massive data-flows in learning systems.

5. IoT

The IoT technology connects various devices such as home appliances, vehicles, or industrial machines embedded with processors, sensors, and network connections. In general, in IoT applications, a lot of sensing information is transferred from IoT devices to servers for further processing. It needs to allocate resources according to data-flows from devices to servers in building IoT applications. The challenge of data-driven resource allocation in IoT is to allocate resources for massive IoT devices since the small size and large scale of data-flows in IoT are different from general computing environments.

Definitions

Data-driven security means that in an environment where all decisions and processes are determined by data, security professionals promote the

behavior of security programs by balancing the following factors: selecting and deploying effective security measures, working within budget limits, and reducing liability exposure.

Historical Background

It has been long time since researchers began to learn from data, but data-driven security was just proposed in twenty-first century (Zhang et al. 2011). According to the way of data utilization, data analysis and processing technology in solving network security problems has gone through three phases so far (Jacobs and Rudis 2014). The primary application area of the first phase is intrusion detection. In particular, according to the difference of data source, intrusion detection technology is divided into host intrusion detection and intrusion detection based on network (Huang 2018). According to the method of data analysis (Comaniciu 2003), it can be divided into the detection based on misuse (feature) and the detection based on anomaly (Tu and Zhu 2002; Tu 2002). Meanwhile, data mining and machine learning began to be applied to test and defend the invasion of network and system (De Vries et al. 2010). Data mining or machine learning essentially establishes a classifier model so as to output the different classification results by identifying the input data (Nivre et al. 2007; Kim et al. 2018; Matusik 2003). The representative product form of the second phase is SIEM (Miller et al. 2010). To unify security information and event management, the first step is to collect the alarm information of different intrusion detection systems and products for correlation analysis (Nath et al. 2010). Then information with operational capability is excavated, so that the security experts, operators, and managers can take timely and effective response measures to deal with more complex network security situational changes. As the data analysis technology improving, the data-driven security begins to attract network and information security specialists to study on it. Nowadays, data-driven security has been applied in many aspects, such as finance, health service, industry, education, and so on. And the

data-driven security technology is playing a more and more significant role in information security defense area, including instruction detection, exploit and analyze vulnerability, fraud detection, phishing attack detection, and spam detection. Due to the qualitative change of underlying data and computing ability, now the data-driven security products can also make an analysis on source code, binaries, and huge amounts of unstructured data such as audio and video and image. The time span of correlation analysis is no longer limited to the hour or day level, but it is increased to the level of the month or year (Fan et al. 2014).

Foundations

Data-driven security is of great significance to cyber security, especially in the era of big data. Today, data is a treasure filled with information instead of binary numbers. Similarly, the advantages of big data are also used in the field of cyber security in business and scientific research. Including security audit, cyber security situational awareness, log analytics, network attack tracing, and so forth, related security technologies have been further improved in intelligence. In this situation, complex security issues can be quickly resolved. However, it will also face new challenges in practice as follows:

1. **Big Data Processing.** Big data is often accompanied by heterogeneity, high dimensionality, heterogeneity, storage bottleneck, and noise accumulation (Fan et al. 2014). Therefore, if there are no appropriate tools and methods for data collection, processing, and storage, then the security analysis work will be extremely difficult (Si et al. 2011).
2. **Programming and Security Technology for Big Data.** People generate data from various behaviors on the web, such as web browsing, upload and download, instant messaging, live broadcast (Zhang et al. 2005), etc. The required analytical capability far exceeds that of traditional safety methods and tools. Thus, it is necessary to find programming and

security technologies that adapt to big data (Jacobs and Rudis 2014).

3. **Methodology for Mining Security Issues.** Data itself is worthless, and it just consists of a large number of characters in various ways. We can use the value of data only when we refine the data into effective information and further sublimate them into knowledge. Therefore, statistical knowledge and techniques as data mining methodology are indispensable for cyber security.
4. **Information Overload.** It easily leads to information overload problems during data mining, especially when the data is getting bigger. Although there is a lot of effective information, we cannot make good use of it. To this end, security visualization technology is urgently needed to solve this problem.

At present, most researches focus on solving the above problems. Therefore, the researches are mainly divided into the following four categories:

1. Data Management

Data Management is a collection of practices, concepts, procedures, and processes that allow for an organization to gain control of its data resources. It is involved with the entire lifecycle of a given data asset from its original creation point to its final retirement. And the Data Management Body of Knowledge (DMBOK) (Mosley et al. 2010) refers to data management as “The planning, execution, and oversight of policies, practices and projects that acquire, control, protect, deliver, and enhance the value of data and information assets.”

Data operations management is a central function of the entire data management framework. And it is defined as the development, maintenance, and support of structured data, which can maximize data resources’ value to the enterprise (Han et al. 1993).

While the above definition says structured data, the definition needs to be expanded to include semi-structured and unstructured data that now exists due to the rise of such contemporary data management trends like big

data, cloud computing, machine learning, data lakes, and the Internet of Things.

The practice of data management includes an extensive list of associated and related topics which span the entire process of managing and leveraging data at all levels. A short list of these includes:

- **Data Governance and Data Stewardship**

Data governance is a data management concept concerning the capability that enables an organization to ensure that high data quality exists throughout the complete lifecycle of the data.

Data stewardship is the management and oversight of an organization’s data assets to help provide business users with high-quality data that is easily accessible in a consistent manner.

- **Data Architecture**

Data architecture is composed of models, policies, rules, or standards that govern which data is collected and how it is stored, arranged, integrated, and put to use in data systems and in organizations. Data is usually one of several architecture domains that form the pillars of an enterprise architecture or solution architecture.

- **Data Modeling**

Data modeling is the process of documenting a complex software system design as an easily understood diagram, using text and symbols to represent the way data needs to flow. The diagram can be used to ensure efficient use of data, as a blueprint for the construction of new software, or for reengineering a legacy application.

- **Data Quality Management**

Data quality management (DQM) refers to a business principle that requires a combination of the right people, processes, and technologies all with the common goal of improving the measures of data quality that matter most to an enterprise organization. That last part is important: the ultimate purpose of DQM is not just to improve data quality for the sake of having high-quality data but rather to achieve the business outcomes that depend upon high-quality data.

The big one is customer relationship management or CRM.

- **Master and Reference Data Management**

Master data management (MDM) is a method used to define and manage the critical data of an organization to provide, with data integration, a single point of reference. The data that is mastered may include reference data – the set of permissible values – and the analytical data that supports decision-making.

Reference data management is a process that drives efficiency across the market by maintaining high data quality standards. It provides full terms and conditions data, including ratings and descriptive content, for each asset types.

- **Data Warehousing**

Data warehousing is the process of constructing and using a data warehouse. A data warehouse is constructed by integrating data from multiple heterogeneous sources that support analytical reporting, structured and/or ad hoc queries, and decision-making.

- **Big Data**

Big data is a term used to refer to data sets that are too large or complex for traditional data-processing application software to adequately deal with. Data with many cases (rows) offer greater statistical power, while data with higher complexity (more attributes or columns) may lead to a higher false discovery rate. Big data challenges include capturing data, data storage, data analysis, search, sharing, transfer, visualization, querying, updating, information privacy, and data source. Big data was originally associated with three key concepts: volume, variety, and velocity. Other concepts later attributed with big data are veracity (i.e., how much noise is in the data) and value.

- **Business Intelligence and Analytics**

Business intelligence (BI) is a technology-driven process for analyzing data and presenting actionable information to

help executives, managers, and other corporate end users make informed business decisions.

Business analytics (BA) is the practice of iterative, methodical exploration of an organization's data, with an emphasis on statistical analysis. Business analytics is used by companies committed to data-driven decision-making.

- **Metadata Management**

Metadata management is the end-to-end process and governance framework for creating, controlling, enhancing, attributing, defining, and managing a metadata schema, model, or other structured aggregation system, either independently or within a repository and the associated supporting processes (often to enable the management of content). For web-based systems, URLs, images, video, etc. may be referenced from a triple table of object, attribute, and value.

- **Data Security Management**

Data security management is a way to maintain the integrity of data and to make sure that the data is not accessible by unauthorized parties or susceptible person to corrupt it. Data security is put in place to ensure privacy in addition or protecting this data. Data itself is a raw form of information that is stored on network servers, on possible personal computers, and in the form of columns and rows. This data can be anything from personal files to intellectual property and even top-secret information. Data can be considered as anything that can be understood and interpreted by humans. Because of the growing use of Internet, there is an emphasis on protecting personal or company data, and this protection is known as data security which can be acquired by using specific software solutions or hardware mechanisms.

- **Content Management**

Content management is a set of processes and technologies that supports the collection, managing, and publishing of

information in any form or medium. When stored and accessed via computers, this information may be more specifically referred to as digital content or simply as content.

A well-developed data management program within an organization has the ability to positively affect change around the administration and use of data assets across all levels, departments, and lines of business. The benefits of data management include improvements of operations management, more effective marketing and sales, better regulation and compliance controls, enhanced security and privacy, reduction of risk across the board, faster application and system development, improved decision-making and reporting, sustained business growth, business and technical alignment, automated and/or streamlined operations, greater collaboration, revenue growth, more consistency across all enterprise processes, and numerous others.

2. Programming and Security Technology

• Programming Technology

Data may come in a wide range of formats, states, and quality. It may be embedded in unstructured or semi-structured log files. Somehow, we must find a way to collect, coax, combine, and massage what we are given into a format that supports further analysis. And learning even basic programming skills opens up a whole range of possibilities when working with data. It frees you to accept multiple forms of data and manipulate it into whatever formats work best with the analysis software you have.

Modern programming language supports basic data manipulation tasks, but scripting languages such as Python and R appear to be used slightly more often in data analysis than their compiled counterparts (Java and C). However, the programming language is somewhat irrelevant. The end results (and a happy analyst) are more important than picking any “best” language. Whatever gets the

job done with the least amount of effort is the best language to use. We generally flip between Python (pandas) and R for cleaning and converting data (or perhaps some Perl if we’re feeling nostalgic) and then R or pandas for the analysis and visualization. In addition, learning web-centric languages like HTML, CSS, and JavaScript will help create interactive visualizations for the web, but web languages are not typically involved in the preparation and analysis of data.

• Security Technology

– Security Audit

It is a systematic evaluation of the security of a company’s information system by measuring how well it conforms to a set of established criteria. A thorough audit typically assesses the security of the system’s physical configuration and environment, software, information handling processes, and user practices. And in the wake of relevant legislations, security audits are often used to determine the regulatory compliance of a system (Rouse 2018).

– Cyber Security Situational Awareness

It refers to an understanding of the cyber threat environment, including how it operates, its associated risks and impacts, and the mitigation measures of these risks. A keen appreciation of the threat landscape can help businesses and individuals to better understand the vulnerabilities so as to adopt early appropriate mitigation measures. We encourage industry players and organizations to have active participation in information-sharing arrangement and collaboration with trusted stakeholders locally and globally for timely and relevant cyber threat intelligence.

– Log Analytics

With data breaches becoming more frequent and sophisticated, protecting customer information and intellectual property is of paramount importance.

The security log analytics solution will enable security teams to gain comprehensive visibility into their environment and detect anomalous behavior as quickly as possible.

Detect anomalous behavior: Early detection of advanced persistent threats and unknown threats.

Minimize exposure: Avoid fines, lawsuits, loss of business and negative PR.

Take quick action: React fast on any abnormal or malicious activity from internal and external actors.

3. The intersection of data-driven security and statistics

Data-driven security is based on the big data, by building prediction models and algorithms based on statistics to determine potential threats and risks. Jeyakumar et al. (2016) constructed an algorithm that used statistics methods to classify the system malware and predict potential malicious attacks by analyzing the processor and memory information of a large number of sample hosts. Interpretation and prediction of classical statistics, also known as feature extraction of data in the field of machine learning, are the core tasks of data analysis, such as ports, protocols, etc., are characteristics of network traffic security analysis. And we need to select the global optimal feature set through the method of optimal subset and stepwise comparison based on statistical principles. At the same time, the work of data-driven security predictions needs to find potential relationships through statistics based on supervised learning and unsupervised learning methods (Cimiano and Volker 2005).

4. Security Visualization

The most effective way to recognize human beings is through visual perception. Therefore, data visualization is used to provide the feedback of analysis for data-driven security.

- Security visualization can identify potential patterns. Some patterns that exist in a single variable or relationships among multiple variables cannot be identified by statistical methods for the reason

that visualization techniques are based on physiologic saccades, which give important information with more visible visual features, making it easy to recognize the intrinsic relationships among variables.

- Security visualization can rapidly complete information transmission. Classical statistical methods such as variance and mean value lose the subtle characteristics of data transfer, while visualization minimizes the loss of data details and enables that communicating millions of point information can be done in a few seconds, facilitating macro and micro safety analysis of data.

Key Applications

Data-driven security is often applied to instruction detection, exploit and analyze vulnerability, fraud detection, phishing attack detection, spam detection, security audit, cyber security situational awareness, log analytics, network attack tracing, and so forth.

Synonyms

[Application of big data on service provisioning](#);
[Big data based service provisioning](#)

Definitions

Service provisioning is the process of configuring a service for customers. It usually associates with telecom industry and cloud infrastructure. The examples of service provisioning are shown as follows.

- When a customer submits a request to use a mobile network, system initializes and manages the customer's services, such as establishing control channels (Huang et al. 2016) and making update scheme for service provisioning due to user mobility (Huang and Guo 2017).
- To activate a low-earth-orbit satellite-based service for secure big data storage, the telecom company has to design and construct the infrastructure for customers in advance (Huang et al. 2018).
- Data centers or edge nodes launch a *Service Function Chaining* enabled machine to meet the customer's subscription, including the desired software and hardware resources, and the access authority in the agreed period (Huang et al. 2017b).
- Cloud infrastructure provider maintains a pool of instances. Customers are allowed to request these instances through application programming interfaces (API) (Xu et al. 2015; Huang et al. 2017a).

Background

Big data promises to reshape the knowledge, society, and economy. The technologies that are used to generate, collect, process, compute, and communicate big data have made significant progresses in the past few years. As an overwhelming volume of data is generated with ever-growing speed every day from various sources and applications, such as cloud services, Internet of Things (IoT), social network services, and other smart terminals, it becomes significant to design, deploy, and provision services that are more wise to enable the effective acquisition, storage, transformation, management, and utilization of such huge amount of data.

To alleviate the violations of *service-level objectives* caused by provisioning delays, inefficient reconfigurations, and inaccurate demand predictions, over-provisioning apparently increases operational costs and resource-utilization inefficiencies, particularly in large-scale systems. Via a data-driven service provisioning framework named AidOps, Lugones et al. (2017) argue that the orchestration system enables a higher service availability and lower over-provisioning costs.

Foundations

As mentioned by Chesbrough and Spohrer (2006), the growing knowledge of information and communication technology (ICT) has created opportunities to inspire the evolution of internet on the service relationships that can yield new value. Specifically, ICT has the following characteristics that can improve effectiveness and efficiency and enable innovativeness in the manners of (1) commoditizing noncore competency such as outsourcing, (2) improving

collaboration in business processes, (3) controlling the risks of information security violation, (4) coordinating service systems such as open innovation platforms, (5) improving customer-oriented service quality, etc. Especially, in the big data era, enormous value can be extracted from the service-oriented big data.

To fully explore the value of service-generated big data, developing efficient technologies that can fast process large amount of data is an open issue. On the other hand, easy access of big data and data analysis results are critical to both service providers and service users (Zheng et al. 2013).

Key Applications

In the following, some typical data-driven platforms/architectures for service provisioning are reviewed.

To provide the functionality of managing and analyzing service-generated big data, Zheng et al. (2013) proposed an infrastructure of data-driven service model. As shown in Fig. 1, a big

Data-Driven Service Provisioning, Fig. 1 Service-generated big data and big data-as-a-service as presented by Zheng et al. (2013)

data-as-a-service framework has been also employed to provide big data services and data analytics results to users. Under this framework, several concrete applications that exploit three types of service-generated big data are illustrating for performance enhancement. First, the service logs generated by service requests can be used to yield visualized log and conduct performance diagnosis. Second, based on the QoS information of each service, fault tolerance and QoS prediction can be performed by service providers. Finally, taking the service relationship into account, significant service identification and service migration are able to realize.

A framework for service-oriented decision support systems (DSS) has been investigated by Demirkan and Delen (2013). By focusing on the product-oriented environment and exploring engineering-related issues, a conceptual architecture of service-oriented DSS is shown in Fig. 2, which includes three service models, i.e., data-as-a-service, information-as-a-service, and analytics-as-a-service. In such a service-oriented DSS solution, the operational systems, data warehouses, online analytics processing, and

end-user components can be provided to users as services either separately or in the bundled manner.

As mentioned previously, a systematic approach named AidOps for capacity provisioning of services in cloud is proposed by Lugones et al. (2017). Instead of on-demand elasticity, AidOps enables service providers to specify a desirable number of reconfigurations (i.e., scaling in/out) as an input, and it then calculates the capacity configurations required to serve the user demand optimally. Figure 3 illustrates the architecture design of AidOps, including system components and interfaces to the cloud and service layers. This system is consisted of a backend and frontend. The former supports data analytics and service provisioning algorithms, while the latter offers configuration functionality to operators. Specially, in the backend, the historical traffic data from operator database is preprocessed to the proper time series format and then fed to the clustering and classification modules for extracting workload patterns. With the pattern database, AidOps predicts daily patterns using a pattern selection module. Finally the predicted time-varying patterns are used

Data-Driven Service Provisioning, Fig. 3

AidOps architecture proposed by Lugones et al. (2017)

Data-Driven Service Provisioning, Fig. 4 An overview of the IoT service model in cloud platforms, as presented by Taherkordi et al. (2018)

to optimize the configuration solution that is demanded by service orchestrator.

Facing the convergence of IoT and cloud, it is significant to facilitate the service provisioning and management in large-scale applications, particularly under the scenario of smart cities. To model and expose cloud-based IoT services in an efficient manner, Taherkordi et al. (2018) proposed CARIoT as shown in Fig. 4, which is a software framework for real-time provisioning of cloud-based IoT services. The main idea behind CARIoT is to structure the description of data-driven IoT services and the service-generated

data, both real-time and historical, in a hierarchical perspective corresponding to the context model of end-user application. With CARIoT, the end-user applications thus can access IoT services and their data in an efficient way.

Important Issues

The important issues under the data-driven service provisioning can be summarized as but not limited to the following topics.

- Efficient models and solutions for querying and processing big data.
- Big data-based service modeling, delivery, deployment, and evolution.
- Analytic services for big data.
- Knowledge discovery over massive datasets.
- Social sensing and social network services.
- Reasoning over uncertain data and unreliable services.
- Big data based service ranking and recommendation.

[Data-Driven Digital City](#); [Data-Driven Intelligent City](#)

Definitions

Data-driven smart city is a cyber-physical system (CPS) that exploits the digital data acquired from a variety of sources to enable intelligent city administration in various domains. The data could be in the forms of government data, citizens' personal data, real-time city surveillance data, etc. By intelligently analyzing these data, it facilitates various city administration decisions such as road planning, transportation scheduling, power control, market regulation, and facility management to promote the quality of urban life from various aspects, e.g., safety, health, greenness, comfort, and efficiency. The rapid development of information and communication technology (ICT) provides a lot of tools to realize the vision of data-driven smart city, covering all the process cycles in data-driven smart city applications, i.e., data acquisition, data communication, data storage, data analytics, decision-making, and actuation. Based on these technologies, many

data-driven smart city applications have been proposed, implemented, and applied in different areas.

Historical Background

The concept of smart city was first formally proposed by IBM in 2008. Thereafter, smart city has been widely put into practice. In 2009, IBM and Dubuque initiated the project to cooperatively build the first smart city (Naphade et al. 2011). In 2009, the US government also initiated the smart grid project to empower the power delivery with ICT technologies (Chen et al. 2009). In the same year, China initiated the launch of project “Sensing China”, which intends to ubiquitously explore the power of IoT technologies. In 2010, the EU’s Horizon 2020 program treat smart city as one of the main development directions (Li et al. 2015). In 2011, Japan announced the “i-Japan” strategy, which intends to incorporate digital technologies into daily lives (Paskaleva 2011). Besides, along with the development of various ICT technologies, the smart city was incrementally re-defined by incorporating the newly emerging technologies. Without doubt that IoT is the first driving force of smart city and it is also the key to enable data-driven smart city by digitalizing the things in the city. Cloud computing then was incorporated to bear the data processing tasks (Parwekar 2011). Due to the long delay and unpredictable jitter of cloud computing, edge computing then was introduced to support delay-sensitive data-driven smart city applications (Gu et al. 2017). Besides the infrastructure innovations, Artificial Intelligence (AI) technologies was also introduced to empower the data processing capabilities (Wu et al. 2016) and future networking technologies was incorporated to support vast connections in smart cities (Tong et al. 2015).

Enabling Technologies

Data-driven smart city leverages various information technologies such as Internet of

Things (IoT), cloud computing, big data, and machine learning for urban planning, construction, monitoring, and management towards green, comfort, efficient, and sustainable city development. Data-driven smart city basically is a CPS that is data-centric. Data generation, transmission, storage, and processing are the key phases in data-driven smart city applications. Many related enabling technologies have been proposed and applied in these phases. For example, IoT technologies support the data generation from the physical world. Various wireless communication technologies and standards provide a variety means of data transmission means. Cloud computing provision an extremely large pool of computation and storage resources and edge computing alternatively provision the computation and storage resources in the citizen proximity. A diverse of artificial intelligence (AI) technologies are available for analyzing the data to provide various demanded city administration decisions.

Internet-of-Things

IoT interconnects various kinds of data generation devices, e.g., radio frequency identification (RFID), sensors, capable of identification, location, tracking, monitoring to realize the synergy between the physical world and the cyber world. As one of the key enabling technologies in data-driven smart city, IoT is used to acquire the desired information in every corner of the city. For example, we can use IoT to surveil the city environment; to monitor the structure health of the road, bridge, and buildings in the city; to manage the grid of the city; and to watch the water distribution system in the city (Zeng et al. 2016b). India and IBM cooperatively developed a real-time water quality management system called “Swatchpaani,” which is powered by IBM’s Watson IoT. Many IoT devices are injected in the water distribution system to continuously monitor water quality via measuring pH, temperature, and the presence of substances (Sandha et al. 2016). The IoT data are essential to build data-driven smart city applications and shall be efficiently acquired and processed.

Wireless Communications

Data-driven smart city applications heavily rely on the data, not only from the IoT devices but also from the human beings (e.g., social network information). The data are usually acquired via wireless communications, which have been developed for several decades. Many wireless communication standards targeted at different application fields have been proposed. Previously, wireless communication or mobile communication standards are usually designed with objectives like high throughput, low latency, high reliability, and low energy. To data-driven smart city applications, it is highly recommended that the new standards shall be with the capability of vast connections such that not only human-attached devices (e.g., mobile phone) but also a large number of IoT devices can be simultaneously connected in the 5G networks for seamless integration of the physical world and cyber world (Tong et al. 2015). The IoT business even may become the main driving force of the 5G networks, which shall support as the base infrastructure for data-driven smart city.

Cloud Computing

Cloud computing provisions computing and storage services in the datacenter in a centralized manner. There are three kinds of cloud computing service provision paradigms, i.e., software-as-a-service (SaaS), platform-as-a-service (PaaS), and infrastructure-as-a-service (IaaS). To data-driven smart city application development, it is also desirable to host the data processing and storage functions in the cloud. Specially, many existing cloud services can be also utilized to mashup more powerful smart city applications. For example, we can mashup the map service with the traffic information acquired via various kinds of sensing devices (e.g., carmounted GPS, surveillance cameras, radar devices) to build an augmented city traffic map for a real-time understanding of the city traffic condition. Based on such augmented map, smart traffic control can be applied to manage the traffic lights for more efficient traffic control. To utilize the huge computing resources in the cloud datacenter, many different kinds of programming frameworks, e.g.,

MapReduce, Storm, are also available. These frameworks provide promising solutions for big city data processing to build data-driven smart city applications.

Edge Computing

Edge computing, as complementary to cloud computing, pushes forward the cloud computing to the network edge such that the computing can be within the proximity of end users for fast data processing (Zeng et al. 2016a). The edge computing servers can be colocated with the access networks, e.g., base stations. Edge computing is characterized by low latency and high bandwidth. Such features are consistent with the requirements of many data-driven smart city applications that require fast data processing and prompt response. For example, one of the most promising smart city applications is auto driving. A huge volume of data shall be processed in a prompt way and cloud computing is not desirable any more with the consideration of limited bandwidth, unpredictable long network delay, and unstable network connections. Resorting to edge computing to provision the computing resources at the network edge becomes a promising solution.

Artificial Intelligence

AI technologies have been developed for several decades and many different machine learning technologies with different capabilities have been proposed and applied in different domains, e.g., decision tree, support vector machine, neural network, Bayesian networks, reinforcement learning. Deep learning, as a newly emerging machine learning technology, further enhances the capability of machine learning in dealing with more complicated tasks. To data-driven smart city applications, AI plays a critical role in data-driven smart cities as these technologies have shown great potential in data analytics for prediction, inference, and decision-making. Specially, modern AI technologies are usually integrated with big data processing technologies so as to excavate the value of data to enable data-driven smart city (Wu et al. 2016). For example, we may apply deep reinforcement learning to

intelligently control the traffic lights according to the real-time information from the augmented map (Wu et al. 2017).

Application Domains

Having the advanced information, communication, and control technologies as backbones, data-driven smart city can be applied in a set of different application domains, including, but not limited to, smart transportation, smart healthcare, smart environment, smart living, and smart governance.

Smart Transportation

Smart transportation mainly focuses on the informationization of urban traffic. It provides data support for decision-making activities through the collection, transmission, and analysis of traffic related data, including both real-time and historical ones. Through the effective integration of various information technologies in traffic management, it provides the citizens with intelligent routine planning, traffic light control, road network structure suggestions. In the upcoming auto driving era, smart transportation shall further perform as the base infrastructure to support the intelligent operation, planning, and management of auto driving cars.

Smart Healthcare

Smart healthcare utilizes IoT technology to realize the interaction between the patients, medical institutions, and doctors to realize real-time, intelligent, and automated dynamic healthcare services (Gu et al. 2017). For example, smart healthcare centers can integrate patient health records from multiple sources to enrich the healthcare database for more advanced disease diagnosis. Smart healthcare also relies on data from connected medical devices, some of which are usually wearable sensors. These sensing data, combined with the surrounding environment information, are essential to many disease diagnosis and treatment. With smart healthcare, the citizens can receive more accurate treatment, thanks to the big healthcare data, and

in a more efficient and on-demand way, thanks to the tele-health system supported by the advanced information technologies.

Smart Environment

Smart environments aim to improve the sustainability of cities, the quality and safety of citizens' lives. Ubiquitous sensing and intelligent climate management are jointly applied in smart environment applications. This enables the timely detection of unhealthy or hazardous conditions and allows the authorities to react accordingly. For example, smart water distribution system utilizes contaminant detection sensors to detect water pollution or contamination and applies depollution actuation to ensure the safety of the citizens. Furthermore, sensor networks can detect natural disasters such as earthquakes, volcanic eruptions, tornadoes, floods, and forest fires. Early warning systems can significantly contribute to limiting casualties and reducing property damage.

Smart Living

In some areas, smart living offers intelligent management of various appliances and utilities to create comfortable homes and improve energy efficiency simultaneously (Liu et al. 2015). Smart living enables remote control of home appliances, especially intelligently in conjunction with the information about the climate change, energy provision, people's daily schedule, and social network data. In the community (or building), smart living applications also intelligently manage waste recycling, social networking, and parking to provide a smart community (or building) with comfortable lives.

Smart Governance

Smart governance aims to build a new and innovative government service platform to achieve a harmonious society with government guidance, market, and citizen participation, making public services more refined, socialized, and intelligent. For example, open data enables citizens, third-party developers, and the city council to access and cross-reference different data sources, which can increase both transparency and efficiency. Smart governance services allow citizens to

complete most interactions automatically, e.g., booking weddings, applying for social housing, resident parking permits, or schools. It also allows citizens to get involved in the city planning and development processes to improve the quality of city life.

Delay-Tolerant Network Routing

Yue Cao
School of Computing and Communications,
Lancaster University, Lancaster, UK

Synonyms

[Mobility](#); [Opportunistic encounter](#); [Routing](#)

Definition

Delay-tolerant network routing utilizes “store-carry-forward” mechanism to relay data, through asynchronized and opportunistic encounters between pairwise nodes. The criterion on selection of relay node is based on various strategies with network topology or geographic information.

Historical Background

Due to the characteristic of challenged environment suffering from frequent link disruption, sparse network density, and limited device capability, routing algorithms designed for mobile ad hoc networks (MANETs) cannot perform effectively under these constraints. This is because the availability of contemporaneous end-to-end connectivity is essential for conventional routing algorithms such as ad hoc on-demand distance vector (AODV) (Perkins et al. 2003) or dynamic source routing (DSR) (Johnson and Maltz 1996). However, such does not prevent bridging communication between the disconnected areas by following the technologies from delay-tolerant networks (DTNs) (Cao and Sun 2013) to overcome these difficulties using the store-carry-forward (SCF) routing mechanism.

In DTNs, mobile nodes can communicate with each other, even if the contemporaneous end-to-end connectivity is unavailable. Furthermore, the global knowledge about network is not mandatory for network nodes in DTNs. The lack of contemporaneous end-to-end connectivity prevents the conventional routing algorithms designed for MANETs from working effectively. Here, the Bundle Protocol (Scott and Burleigh 2007) borrowing from the concept of Email protocol is proposed by the Internet Research Task Force (IRTF) Delay-Tolerant Networking Research Group (DTNRG) to behave as a convergence layer protocol on top of the Transmission Control Protocol (TCP) layer to enhance the transmission reliability in DTNs.

Delay-Tolerant Network Routing, Table 1 Comparisons between routing in MANETs and DTNs

	Routing in MANETs	Routing in DTNs
End-to-end connectivity	Contemporaneous	Frequently disconnected
Delivery delay	Short	Long
Transmission reliability	High	Low
Routing behavior	Symmetric	Asymmetric

It is worth to note that other terms, e.g., intermittently connected networks (ICNs) (Khabbaz et al. 2012) or opportunistic networks (Pelusi et al. 2006), were proposed by other articles, while they are normally exchangeable with DTNs. As illustrated in Table 1, routing in DTNs suffers more from long delivery delay than that of MANETs due to the asymmetrical routing behavior and low transmission reliability while taking into account the limited encounter duration due to the lack of contemporaneous end-to-end connectivity.

Foundations

Useful Terms

Encounter opportunity: It is an encounter between pairwise nodes. Specifically, an encounter opportunity is regarded as a tuple consisting of (d, m, b) , where d is the time duration of an encounter, m is a set of messages requested for transmission, and b is the bandwidth speed of DTN device. For reliable transmission, the total size of messages m being transmitted during an encounter opportunity should not exceed the maximum volume of the encounter opportunity, which is determined by $d \times b$.

Store-carry-forward: When a node carries a message, while there is no contemporaneous end-to-end path to its destination or even a connectivity to any other node, this message would be stored locally. The sender would wait for the upcoming encounter opportunity with other nodes for message relaying.

Candidate node: Based on the definition of store-carry-forward, the encountered node selected as the message relay is defined as the candidate node for this message.

Inherent Challenges

Bandwidth: This factor determines the number of messages that can be transmitted at each encounter opportunity. For instance, if the bandwidth of a DTN device is sufficient to transmit all the requested traffic load within a given encounter duration, then this is reasonable. However, if the traffic load increases due to a large number of users or a larger size of messages being transmitted, then the unsuccessful transmissions due to insufficient encounter duration should be taken into account. Therefore, to estimate the number of messages that can be successfully transmitted is useful to reduce the number of aborted messages due to insufficient encounter duration. In addition, to transmit messages according to a corresponding priority is beneficial to utilize the bandwidth.

Buffer space: The sufficient buffer space is essential for the carried messages, since they would be buffered for a long period time until the upcoming encounter opportunity is available. In light of this, to discard the least important message due to buffer space exhaustion is beneficial to utilize the buffer space.

Energy: A DTN device often has limited energy and cannot be connected to the power supplier easily. Energy is required for transmitting, receiving, and storing messages and performing routing process. Hence, the DTN routing algorithms which transmit few messages and perform less computation are more energy efficient.

Mobility Model

Apart from the inherent challenges, mobility factor (Grossglauser and Tse 2002) describes the variation of movement and plays an important role in routing performance in DTN. Therefore, it is desirable to emulate the movement pattern of

the targeted real-world applications in an appropriate way. Otherwise, the conclusions and observations drawn from the results may be misleading. In light of this, it is necessary to select the appropriate underlying mobility model while evaluating the routing performance. For example, the mobile nodes under the random Waypoint (RWP) mobility model would behave differently from the group-based mobility model. In reality, since it is difficult to obtain the global knowledge about the distribution of encounter probability or inter-meeting time, knowledge and assumption regarding mobility model are more crucial.

Evaluation Metrics and Routing Objective

Delivery ratio: It is given by the ratio between the number of delivered messages and the number of generated messages.

Overhead ratio: It is given by the ratio between the number of message transmissions required for delivery and the total number of messages delivered.

Delivery delay: It is given by the time duration between the message generation and their delivery.

The routing objective provides a trade-off between maximizing the delivery ratio and minimizing the overhead ratio. On one hand, the ideal case of delivering the message before its given lifetime with the lowest overhead ratio is to keep this message until the destination is in proximity. While on the other hand, the effective approach to maximize the message delivery ratio is to relay this message at each encounter opportunity (if necessary, taking into account the candidate node selection strategy). Although it is expected that the applications of DTNs are inherently tolerant to the long delivery delay, this does not mean they would not benefit from short delivery delay; thus this should be a still target with the given message lifetime.

Summary of Routing Protocols in DTN

Literature works have formed the following two mechanisms during routing procedure:

Single copy-based: The data is normally relayed through several candidate nodes toward

the receiver. During the routing procedure, there is no message copy generated. The performance of routing protocols under this mechanism is substantially influenced by nodal mobility model, where infrequent encounter opportunity between nodes may result in failure of data delivery.

Multiple copy-based: A number of copies of the message will be generated. This is driven by the aim that at least one of these copies will be delivered, through multiple paths formed by opportunistically selected candidate nodes. The routing performance with this mechanism is greatly improved particularly in networks which are quite sparse. The downside is a significantly increased routing overhead incurred by exchanging of message copies.

Naturally, based on what knowledge used for making routing decision, DTN routing protocols are classified into following two branches.

Topology-Based Routing Protocols in DTNs

There have been many previous works address this technique branch, in (Cao and Sun 2013) several metrics have been reviewed to guide with design of routing protocols.

The one-hop encounter featured routing protocols rely on one-hop prediction, e.g., direct encounter probability or encounter interval/frequency, to qualify the candidate node, while the time-varied shortest path-based routing protocols expect a global view about the knowledge such as queue size and inter-meeting time of other nodes in the network. Using these information, a classic Dijkstra's approach forms a path consisting of opportunistic encounters with the time-varying property. Apart from this, the social relationship-based metric considers the social tie among the linked nodes. As such, many existing methods from online social networks have been applied in DTN routing.

Besides, the assumption of traditional congestion control approach is based on the contemporaneous end-to-end connectivity, enabling both the congestion feedback and control information to be received timely and successfully. Since it is difficult to perform this end-to-end-based approach due to the constraints in DTNs, the hop-by-hop approach is appropriate instead.

This gears the routing protocol with the nodal resources constraints like buffer and bandwidth to discard incoming/carried data, reduce the number of copies of data, and alternatively transfer the data to another temporary candidate node to help hold the data.

In summary, the above-featured routing protocols estimate how reliable that pairwise nodes will encounter and communicate. A good candidate reflects it will meet the current data carrier with a short time interval but high frequency, of course a long communication duration in each encounter is a plus for reliable data transmission.

Geographic-Based Routing Protocols in DTNs

Geographic routing (Karp and Kung 2000), also called position-based routing, requires that each node can determine its own location and the source is aware of the location of destination. Different from topological routing, geographic routing exploits the geographic information instead of topological connectivity information for message relay to gradually approach and eventually reach the intended destination. However, the design of geographic routing (Wang et al. 2016) in DTNs inevitably faces the following challenges:

- In DTNs, the network node which is currently closer to the destination may not be still a good candidate node in the future. This is because that it may move away from the destination within a short time, particularly concerning the high mobility in sparse network.
- Concerning the mobility of destination, it limits the feasibility of applying a centralized location server to track the real-time location of mobile destination in sparse networks. This happens due to the fact that there is a long delay to request/reply the information from location server in DTNs, while the obtained location information may be outdated and inaccurate for making routing decision.
- Conventional geographic routing protocols in MANETs rely on the high network density, which is infeasible in DTNs because there are

insufficient number of encountered nodes for handling this problem. The local maximum problem generally refers to the case that there is no other candidate nodes in proximity, as such the message will be kept locally. In the worst case, the data will expire and get discarded locally.

Key Applications

The space application of DTNs is for InterPlanetary Networks (IPNs) (Caini et al. 2011) with a low network dynamic. In mobile wireless networks, the terrestrial applications of DTNs have been envisioned for vehicular ad hoc networks (VANETs) (Pereira et al. 2012), airborne networks (Jonson et al. 2008), packet-switched networks (PSNs), and underwater networks (UWNs) (Wei et al. 2014).

IPNs: Here, the high bit error rate and long delay of wireless communication condition in deep space scenario are of major challenges.

VANETs: Facing frequent link disruption between vehicles, the exchange of intervehicle information (road traffic, motion, etc.) can achieve safer and efficient driving in VANETs.

ANs: Apart from the major applications in the military work previously, unmanned aerial vehicles can also achieve the image acquisition with high imaging resolution, incorporate with satellite sensing systems to monitor environments in disaster scenario, and also monitor in the development of smart cities.

PSNs: Concerning human routine, with continued and dramatically increased interests in the civil applications alongside collaboration with adjacent sectors, PSNs make use of both human mobility and social relationship connectivity to relay the message between mobile users.

UWNs: Acoustic communication systems differ from terrestrial telemetry, due to differences in system geometry and environmental conditions. With the autonomous underwater vehicles delivering data to sink node, UWNs are envisioned for oceanographic applications such as pollution monitoring, etc.

Future Directions

It has been years since DTN routing has been proposed with numerous contributions investigated. Right now, given the emerging trend of 5G technology, DTN routing is able to support the network performance as complementary role when cellular network infrastructures are in failure. Artificial intelligence (AI) algorithms should be adequately investigated to optimize the routing decision, e.g., machine learning and Bayesian and reinforcement solutions are worth the investigation. Particularly, these technologies would help to predict network condition and variation, so as to switch toward DTN routing or long-range ubiquitous communication. In addition to unicasting routing protocols being mainly studied, multicasting and anycasting should be promoted as well (Cao et al. 2018), e.g., implementing an anycast-based routing protocol in VANETs.

Densification of base stations

Definitions

Network densification is the process of deploying more cells during the development of wireless communication industry, which is by far the greatest contributor to the evolution of network capacity.

Historical Background

The 1970s witnessed the emergence of the first-generation cellular network. Since then, wireless communications have developed into one of the largest sectors of the telecommunications industry and improved humans' living experience in nearly every aspect. It is worth noting that there were only 10 million subscribers in 1990, mostly using analog FM technology (Rappaport et al. 2002). In 2017, the 5 billion mobile subscriber milestone was reached, and a further 620 million subscribers will be added by 2020, reaching almost three quarters of the global population (GSMA Intelligence 2017). With the realization of the Internet of Things (IoT), smartphones are not the only connected devices. Now, the machine-to-machine market is undergoing a fast transformation over the wireless cellular networks. In 2017, IoT connections have outnumbered traditional smartphone connections.

Meanwhile, since the first car phone call was made in 1979, multiple services have been supported by the cellular networks apart from the voice services. For example, the first text message

was sent in December 3, 1992, with a greeting of Merry Christmas through short message service (SMS) of the second generation of mobile technology (2G). Later, multimedia message service (MMS) standard extended the core SMS capability, allowing messages with multimedia content. Mobile Internet data requests were handled by Wireless Application Protocol (WAP) or i-mode in the 1990s, and the first WAP-enabled service hit Europe in October 1999 and i-mode was launched in Japan in February 1999. At that time, checking e-mail or daily news was the premiere application. Now, nearly three quarters of smartphone users globally watch online videos on their phones. A total of 5 exabytes video traffic was transmitted monthly in 2016, and the number was estimated to reach 50 exabytes by 2022 (GSMA Intelligence 2017). Accordingly, the theoretical transmission data rate has increased from 9.6 kbit/s for Global System for Mobile Communications (GSM) in 2G to 1 Gbit/s for Long-Term Evolution (LTE)-Advanced in 4G.

Even though only four decades have passed since the emergence of the first-generation cellular network, wireless communication system has experienced tremendous changes to support such large traffic volume from a multitude of users with diverse service requirements. One obvious change is the development of mobile phones, which originated as car phones, turned to huge heavy portable devices, and finally became modern smartphones.

The evolution of wireless infrastructure equipment, compared to mobile phones, is not that closely linked with humans' life. However, wireless infrastructure equipments have experienced a dramatic change not only in the structure but also in quantitative terms. Looking over the development of wireless network, introducing more cells is by far the greatest contributor to the evolution of network capacity. From 1960 to 2010, deploying more cells has increased the capacity by 2000 times, while using extra spectrum and improving spectral efficiency totally only contribute 50 times in capacity increases (Agilent Technologies 2013).

The intent of this entry is to explore the role of base station densification during the evolu-

tion of wireless system. Initially, increasing the density of macro cells is to meet the coverage and capacity requirement in earlier cellular network. Later, the concept of small cell has been proposed to meet high capacity requirement in certain areas. Since then, the number of small cells has increased dramatically, and this trend is forecasted to continue as the ultradense small cell network has become essential for 5G network. Focusing on the number of base stations, the rest of this entry discusses the benefits and challenges of network densification in homogeneous and heterogeneous networks, respectively.

Homogeneous Networks

In the early days of cellular network, only macro cells were deployed, which formed a homogeneous network. The typical coverage of a macro cell ranges from 1 to 35 km. In an initial network, planners typically aim at using fewest possible base stations to provide the maximum coverage. As subscribers increase, planners need to optimize network capacity, and cell size should be as small as possible to accommodate additional capacity. Thus, the development of homogeneous network can be roughly divided into two stages based on the different planning focuses, i.e., coverage planning and capacity planning.

Stage 1: Coverage Planning

The initial period of the first-generation cellular network can clearly show the premier coverage concern of network planners. For example, 88 cell sites were deployed in the first commercial cellular network launched by Nippon Telegraph and Telephone (NTT), a Japanese telecommunications company, on December 1, 1979, with a fully functional network covering the 23 wards of Tokyo. Fifty-six cells and 36 cells were distributed, respectively, by AT&T and Motorola to cover New York city using advanced mobile phone system (AMPS). However, in the 1970s and 1980s, even though the rational coverage was claimed in different countries, most mobile phones only worked when they were close to a base station.

The first generation of analog cellular network was gradually replaced by the second generation of digital network since the commercial launch of the GSM service in 1991 with limited coverage of larger cities/airports in Europe, followed by a complete linking of areas by 1995. Since Telstra Australia became the first non-European operator to sign the GSM in 1993, GSM networks went live globally, and the milestone of 1 billion subscribers was reached in 2004. Even though 2G services are gradually replaced by new technologies, for example, NTT DoCoMo in Japan terminated its 2G services on March 31, 2012, 2G network still shares the highest coverage rate and the largest connected population, which is 40% of total connections in 2017 (GSMA Intelligence 2017).

Only four decades have passed since the emergence of 1G, and mobile network has almost reached global coverage. Today, only a quarter of the global population lack access to wireless network, and the majority of these uncovered population live in the rural regions of Asia and sub-Saharan Africa, and it is uneconomical to extend coverage of these area due to the high fixed costs of laying network infrastructure to serve sparsely distributed population with low purchasing power.

Stage 2: Capacity Planning

With the increasing number of subscribers, only ensuring the network coverage cannot meet the transmission requirements from massive users. For example, theoretically, 30 cells are needed in GSM system to support 10,000 subscribers; if the grade of service (GOS) is 2%, and the number of available channels is 24 (Ericsson 1998). When the number of subscribers surpasses the system limit, network planners need to make amendments to the existing system to increase the network capacity.

There are multiple approaches to improve the network capacity, and one direct method is to deploy more macro cells. However, it is too costly to rebuilt a new network with more base stations. In this case, applying cell splitting becomes a practical approach. Cell splitting is the process of subdividing a congested cell into smaller

cells such that each smaller cell has its own base station with reduced antenna height and reduced transmitter power. This method increases the capacity of a cellular system and minimizes the need to modify the existing cell parameters. However, there are challenges in increasing the capacity by cell splitting. As more cells are deployed, handoffs are more frequent, and the process of channel assignment becomes more difficult. Meanwhile, as all cells are not split simultaneously, special care should be taken for proper resource allocation.

Apart from splitting macro cells, adding sectors is the other way to increase network capacity, which replaces the omnidirectional antenna at each base station by three (or six) sector antennas of 120 (or 60) degrees opening (Babich and Vatta 2002). Correspondingly, the channel set serving this cell has also been divided, and thus each sector is allocated one-third (or one-sixth) of the available number of channels. Cell sectorization is less expensive than cell splitting, as no new base stations are required. Comparing to using omnidirectional antenna, this technique can reduce co-channel interference and thus increase the capacity. For example, comparing to using omnidirectional antenna, the network capacity is 1.5 times by using 60-degree sectored antennas (Small Cell Forum 2016). Meanwhile, using cell sectorization enables the reduction of the cluster size and provides an additional freedom in assigning channels. However, by dividing the bigger pool of channels into smaller groups, trunking efficiency is decreased due to sectoring, and the handoffs among different sectors are essential.

Heterogeneous Networks

Apart from adding more sectors or macro cells, an alternative approach to expand an existing macro-network is to introduce different kinds of small cells, such as femtocells, picocells, and microcells. Small cells are low-powered radio access nodes with a range of 10 meters to a few kilometers. The deployment of small cells within the coverage of macro cells can improve the

area spectrum efficiency greatly by reusing the same frequencies many times within a geographical area. The result is a heterogeneous network (HetNet) with large macro cells guaranteeing the network coverage and small cells providing increased capacity per unit area. The concept of small cell has already been proposed in GSM and supported by the LTE specifications since the beginning of LTE. Since then, HetNet has replaced the position of homogeneous network gradually and become the basic network structure for modern wireless system. The development of HetNet can be roughly divided into two stages based on the density of small cells, which will be discussed, respectively.

Stage 1: Sparse Small Cells

The primary purpose of adding small cells is to increase capacity in hot spots with high user demand or to fill the coverage gap in bland spots and cell-edge areas, both indoors and outdoors. Thus, during the early period of HetNet, small cells are deployed sparsely and separately.

The main challenge of deploying small cells within the coverage of macro cells is to tackle the interferences between macro and small cells, which are also referred as cross-tier interferences. A number of approaches can be used to mitigate the cross-tier interferences, and the three dominant methods are inter-cell interference coordination (ICIC), carrier aggregation (CA), and coordinated multi-points (CoMP), which have all been added into 3rd Generation Partnership Project (3GPP) LTE specifications. ICIC and its successors, enhanced ICIC (eICIC), and Further enhanced ICIC (FeICIC) were introduced in 3GPP Release 8, 3GPP Release 10, and 3GPP Release 11, respectively. The former concentrates on the frequency domain to decrease the interference by lowering the power of a part of subchannels of macro cells, and the latter two introduce a blanking of subframes of the macro cells in the time domain to mitigate the interferences. Apart from ICIC-related approaches, the other method is to apply CA with cross-carrier scheduling, which enables that user equipments can connect

to different base stations (macro cell and small cell base stations) on different carriers on the physical downlink control channel (PDCCH). CoMP, on the other hand, focuses on the collaboration between macro cells and small cells. For example, data can be transmitted simultaneously from different base stations to the same user equipment in the same resource block.

At the end of the previous section, the main challenge of achieving global coverage has been pointed out, which is the uneconomical factor to build network infrastructures in rural or remote areas to serve sparsely distributed populations with low purchasing power. In this case, the usage of small cell technology represents an economical alternative. For example, SoftBank Mobile, the Japanese mobile operator, has installed thousands of small cells throughout rural Japan by 2016. In the UK, Vodafone's rural Open Sure Signal project also deploys small cell in rural areas, and each unit provides up to 500 m of 3G coverage.

Stage 2: Dense Small Cells

Initially, few small cells are deployed sparsely and separately to provide high capacity in hot spots or fill the coverage gap. But now a large number of small cells are distributed where demand dictates, such as in cities, remote areas, workplaces, and leisure locations, and are starting to appear in vehicles and even drones. At the end of 2012, the number of small cells has surpassed 6 million (6,069,224), which outnumbered that of macro cells (5,925,974). Meanwhile, the density of small cell increases with time, and the hyperdense small cell network is believed to be essential to address the data surge in future network. In 2014, among the 207,000 urban small cells, about half of them (118,000) were sparsely distributed, and there is no hyperdense small cell network (Rethink Technology Research 2017). In 2016, the number of urban small cells reached 1 million, with one forth (256,000) sparse small cells and one tenth (112) hyperdense small cells (Rethink Technology Research 2017). With the start of rollout of 5G hyperdense zones of

capacity, the installed small cells will leap to about 14.5 million by 2022 (Small Cell Forum 2016), with 2 million hyperdense small cells (Rethink Technology Research 2017).

There are multiple challenges with the densification of small cells, and the construction of small cell backhaul network consistently appears high on the list of operator perceived barriers (Small Cell Forum 2017). Both wired and wireless backhaul technologies can be applied to connect small cells and macro cells with a stable, affordable, scalable, and high data rate link. Wired backhaul solutions, such as fiber and copper, provide optimal capacity and reliable connections. However, the biggest restriction is that it depends on a pre-established infrastructure, and such infrastructure exists mostly in residential and enterprise area, that is to say, indoor scenario. Meanwhile, using public Internet connections presents a security risk. In area without pre-established infrastructure, operators have to build their own wired backhaul network, which is time-consuming and costly. For example, it takes about 2 years for the Verizon Communications, an American telecommunication company, to establish the small cell network in several large cities in the USA, as every single cell has fiber backhaul to a macro cell. In cases like these, operators in need of quick deployments will generally choose wireless solutions, such as traditional microwave (6–42 GHz), sub 6 GHz microwave, unlicensed millimeter wave (60 GHz), and E-band microwave (70–80 GHz). Even though all these solutions for small cell deployments are available on the market, there is no uniform standard for this fast-growing market.

Conclusion

Only four decades have passed since the emergence of the first analog cellular network, and now there are nearly 7 million macro cells and more small cells globally. The densification of base stations is believed to be the greatest contrib-

utor to the evolution of network capacity. In the early period of cellular network, only macro cells existed and constituted a homogeneous network. One way to expand an existing macro-network, while maintaining it as a homogeneous network, is to densify the network by adding more sectors per cell (cell sectorization) or deploying more macro cells (cell splitting). However, reducing the site-to-site distance in the macro-network can only be pursued to a certain extent, and an alternative is to construct a heterogeneous network by adding different kinds of small cells. The main challenge in this stage is to tackle the interference between small cells and macro cells, and different approaches, such as ICIC, CA, and CoMP, have been added in LTE and LTE-A specifications to support heterogeneous network. With the fast-growing demand for high data rate, deploying high-density small cell network becomes an attractive solution, where the density of small cell base stations can be equal to or surpass the density of user equipments. There are many remaining challenges to deploy a high-density small cell network, and the construction of backhaul network consistently appears high on the list of operator perceived barriers. Different wired and wireless backhaul products are available in the market, and there is no uniform standard yet.

Even though every generation of cellular network has undergone the process of densifying base stations to meet the coverage requirement and then the capacity requirement, different approaches have been applied. 1G was purely consisted of homogeneous network, and the approaches of cell sectorization and cell splitting were proposed in 2G to increase the network capacity. Meanwhile, heterogeneous network planning was already used in 2G, where macro and small cells were allocated different frequencies to avoid the cross-layer interference. More effective solutions have been proposed to support heterogeneous network in 3G and 4G, and gradually, heterogeneous network has become the basic network structure. Since the emergence of small cell, its application scenarios have been enlarged continually, and deploying dense small cells has become a trend for 5G.

Key Applications

Network densification is essential in every generation of wireless communication system.

Synonyms

[Placement strategies of cellular networks](#)

Definitions

The deployment strategy of cellular network is a complete plan that includes evaluation mechanisms, processes, and algorithms to deploy base stations of cellular network. The aim of evaluation mechanisms is to assess the performance of deployment solution that the user can notice the improvements barely. The common definition of process is a series of actions to achieve deployment goals, and the algorithm is brought up for mathematical instructions or rules that are designed according to deployment goal.

Historical Background

In order to cover the communication range of large areas, the early mobile radio systems generally adopt high-power transmitters and then built them in higher geographical locations. However, the used frequency bands in the covered area could not be reused since they may cause interference when other transmitters used the same frequency band at the same time. In the healthcare field, some reports show the high-power waves may cause harm to human bodies. Therefore, the concept of a cellular network has been proposed to solve the above problem (Jump and Kirtane 1974). Each cell of a cellular network has a radio base station (RBS), which is called Node B in 3G and eNB in LTE. Radio base station will be connected to the core network through a fixed network (optical fiber) to replace the traditional single high-power base station. Because the coverage area of the cell is small, the transmitter does not need high power to transmit data so that the damage on human health also can be reduced. Different cells can use different bands to improve spectrum utilization. Because the distances between cells are far enough, the interference problems also can be avoided.

With the rapid development of the Internet, people's demand for the network has gradually increased. In order to achieve the goal that the people can access network anytime and anywhere, the network coverage rate has become

a problem that cannot be ignored. Therefore, many cells with different coverage areas have been developed. The coverage range of cells from large to small can be divided into macrocell, microcell, picocell, and femtocell. Among them, microcell, picocell, and femtocell are also called small cell. Macrocells must be operated under licensed spectrum. Small cells, which can be used to supplement for the noncoverage area of macrocells, can be operated in licensed and unlicensed spectrum. The deployment cost and restriction of services number are different with different cells, and the deployment position of RBS is limited by the environment. Furthermore, the spectrum allocation is also a challenge because interference will happen when the same band is used by two cells. Therefore, the deployment problem of cellular network is difficult and complex.

The deployment problems of cellular networks need to be solved by appropriate strategies according to the different goals, the demands, and the environment change. In order to provide a flexible and efficient deployment strategy, it is necessary to include evaluation mechanisms, processes, and algorithms. The evaluation mechanisms need be adjusted according to the deployment goals; for instance, the signal-to-interference-plus-noise ratio (SINR) is usually used to evaluate signal quality; Watts/kbps and Watts/user are used as metrics to quantify the performance of total network power consumption and the ratios (Koutitas et al. 2012). If multi-objective evaluation mechanisms have been adopted, it must consider the interaction between different indicators. For example, the coverage area is inversely proportional to the deployment cost. If the deployed solution with low cost is always chosen, the coverage area cannot be maximum. Therefore, the key point to achieve high deployment quality is to adjust the weight value between indicators as well as strike the balance. In other words, the evaluation mechanism can directly affect the accuracy. The process includes a series of processes that aim to achieve development goals. The design of the steps from the initial environment to the method will affect the effectiveness of the deployment strategy. Algorithms (methods)

usually use mathematical instructions or rules. A apposite algorithm can be adopted to avoid falling into local optima quickly; in other words, the algorithm is able to find the best deployment method for the global solution.

Key Applications

The deployment strategy of cellular network is widely applied. Most goals are based on minimum deployment cost or minimum energy consumption to achieve maximum coverage area, maximum number of service users, and maximum signal quality. In order to cover all the areas, Tseng et al. (2016) adopted macrocell, microcell, and femtocell to design deployment strategy. They proposed the top-down algorithm and bottom-up algorithm. The former aims to provide service to maximum coverage. The latter is to reduce the deployment cost. Furthermore, this study provides the best signal quality for each served user with low construction cost. Because the goal of this kind of problem is to provide Internet access anywhere, it will not take into account the number of users that can be serviced by RBS.

On the contrary, for the maximum number of service problems, the people within the coverage area of RBS cannot access the network likely because the service capacity of RBS is limited and such scenario usually happened in population centers. For maintaining the network performance, Fehske et al. (2009) introduced an evaluation mechanism for area power consumption and area throughput, through deploying a microcell to decrease the area power consumption in the network while still achieving certain area throughput targets. In other words, it can keep the number of service users and minimize energy consumption.

For the maximum signal quality strategy, it is necessary to consider the interference which is caused by obstacles. The obstacles include terrain, buildings, and so on. Klessig et al. (2011) introduced a traffic model that takes into consideration the co-channel interference and non-full load scenarios. Authors adjust the macro site

transmit power to fulfill the coverage condition of 95%, and the efficiency gain is also achieved by 20%.

The deployment strategy of cellular network will be more complex and difficult while network architecture changed. In order to extend the coverage, the concept of relay node has been proposed by Pabst (2004). It can reduce infrastructure deployment and enhance the capacity in cellular networks by using multichip communications via relay nodes.

To sum up, the application of deployment strategy of cellular network is wide and various. Many types of small cell and different network architectures lead to deployment problem and become a complex and important issue. Only providing a completed deployment strategy, the energy consumption and deployment cost can be decreased.

Synonyms

Differential confidentiality; ϵ -Differential indistinguishability; ϵ -Differential privacy

Definition

Differential privacy is a mathematically formal definition of privacy which is used to quantitatively measure privacy loss.

Definition 1 (ϵ -differential privacy) A randomized function A satisfies ϵ -differential privacy (Dwork 2006; Dwork et al. 2006) if for all datasets D_1 and D_2 differing on at most one record, and all outputs $S \in \text{Range}(A)$,

$$Pr[A(D_1)S]e^\epsilon \times Pr[A(D_1) \in S], \quad (1)$$

where the possibility is taken over the randomness of A . The parameter $\epsilon > 0$ is a privacy budget. The smaller the ϵ is, the stronger the privacy protection is Dwork (2011) and Dwork and Roth (2014).

Historical Background

Differential privacy originates from database publication and privacy-preserving data analysis. People can initiate various queries on databases, such as health records, and cross-reference the results with query outputs from other databases to link or even identify a specific user. For example, a practical analysis (Narayanan and Shmatikov 2008) has been conducted on a Netflix dataset containing anonymized movie ratings of 500,000 Netflix subscribers, and it has shown that an adversary with a little background knowledge can easily identify a subscriber's record if the subscriber is present in the dataset. Therefore, a requirement that data records after a database publication cannot be traced back to their owners emerges. Differential privacy guarantees that it will not induce significant difference on the query result whether a data owner is in the database, so the adversary cannot obtain useful information about the data owner. Meanwhile, it gives a formal definition on privacy and how to quantitatively define the privacy level.

Foundations

A key notion of differential privacy is the sensitivity (Li et al. 2017) of a function f .

Definition 2 (Sensitivity) For any function $f: D \rightarrow R^d$, the sensitivity Δf of function f is:

$$\Delta f = \max_{D_1, D_2} \|f(D_1) - f(D_2)\|_1 \quad (2)$$

for all D_1 and D_2 differing on at most one record.

When $d = 1$, Δf is the maximum of the difference in the outcomes that f can query on two neighboring databases. For instance, if f is

a counting function, then adding or deleting a single database record can affect the outcome by at most 1 which means $\Delta f = 1$.

Two known approaches to achieve differential privacy are Laplace mechanism (Dwork et al. 2006) and exponential mechanism. Laplace mechanism is designed for functions whose outputs are real. It takes as inputs a database D , a function f , and a privacy budget ϵ . Specifically, a Laplace noise is sampled and added to the output. The Laplace noise is drawn from a Laplace distribution $Lap(b)$ with a probability density function $Pr[x|\mu, b] = \frac{1}{2b}e^{-(|x - \mu|)/b}$, where μ is the location parameter and b is the scale parameter determined by $b = \Delta f/\epsilon$. Exponential mechanism (McSherry and Talwar 2007) is designed for functions whose outputs are not real. It defines a utility function U which matches a utility score to each output and assigns higher probabilities to be selected exponentially to outputs with higher utility scores.

When taken into joint analysis, a sequence of functions should still provide privacy guarantee. There are two properties (McSherry 2009) of differential privacy regarding composition: sequential composition and parallel composition. First, there are several functions, and each function gives ϵ -differential privacy separately. A sequence of these functions gives $\sum_i \epsilon_i$ -differential privacy; second, if the sequence of functions is conducted on disjoint databases, then the final privacy budget is not an accumulated value but determined by the biggest privacy budget.

Key Applications

Differentially private distributed online learning for wireless big data. In a scenario where many sensor nodes are deployed in a rain forest and each node senses the environmental data, i.e., air temperature (Li et al. 2015) and precipitation. These data are locally processed to predict the rainfall because uploading this large scale of data will incur heavy communication overhead for typical wireless sensor networks. When the nodes are making predictions with online learning and

distributed convex optimization, they have to exchange weighted parameters with neighboring nodes at each round and update local parameters. However, since the nodes are subject to capture attack in a wild and unattended operation area, communications among nodes may leak the localization of nodes. A random Laplace noise can be added to the local parameter to guarantee differential privacy which is also output perturbation. To offset the prediction error caused by partial data and noises, a regret of the algorithm is defined to achieve a faster convergence rate.

Differentially private wireless data publication. Wireless local area networks have been used to evaluate network performance and analyze the user activity pattern since they trace association and disassociation records between users' wireless devices and the networks' access points (Yu et al. 2015). However, these records contain users' sensitive information, such as location and trajectory. Publishing these records without any protection will violate their privacy. Therefore, it is crucial to preprocess users' sensitive information before they are published. The other challenge is that the data utility for data analysis should be guaranteed without conflicting with differential privacy on multidimensional datasets. Suppose a trace database is a table T with w attributes, and it is associated with a joint frequency array A_T recording the statistical information of each attribute in table T . In a sanitization algorithm, a compact synopsis S_T of A_T is built by using multidimensional wavelet transforms. Then, a Laplace noise is added to each element in S_T to generate a noisy array $\hat{S}_T$. Lastly, the reconstruction information is recorded for each element in $\hat{S}_T$ to support query functions. Here, the supported query functions include Count and Sum.

Location privacy based on differential privacy in industrial wireless sensor networks. Industrial wireless sensor networks (IWSNs) are becoming an important component in Industry 4.0. A large number of moving nodes, such as workers and mobile products, are utilized to provide flexibility and mobility. These nodes upload sensing data to a data center to enable process monitoring and decision-making (Wang

et al. 2018). However, data mining technology will bring up the problem of privacy leakage because the data center is considered to be an honest-but-curious entity. For instance, a 3-month study (De Montjoye et al. 2015) on credit card records demonstrated that four spatiotemporal points were enough to recognize 90% of individuals. Meanwhile, how to determine an optimal partition granularity and improve the data utility of location data are other problems for partition schemes based on quadtree or kd-tree. Suppose a data domain is split into $l \times l$ cells $\{c_1, c_2, \dots, c_{l \times l}\}$ and each point number x_i in cell c_i is added by a random Laplace noise. Then, the sanitized database $\hat{\mathcal{D}} = \{\hat{x}_1, \hat{x}_2, \dots, \hat{x}_{l \times l}\}$ is released. Given a location database $\mathcal{D}$ and a privacy budget ϵ , how to improve the data utility comes down to choosing an optimal partition granularity g to achieve a minimal error $\min_g(e_n + e_u)$ of the query function where e_n is the noise error caused by noises and e_u is the nonuniformity error caused by the assumption of uniform distribution. Specifically, g is inferred through the linear-regression analysis, and a granularity partitioning model can be established. Second, a uniform cell release approach is constructed based on the granularity partitioning model. Then, similar cells will be merged into one cell if their hash value difference is smaller than a threshold and a random noise is added to each new cell. Lastly, the perturbed database $\mathcal{D}$ is released for query functions.

Definition

A community is a clustering of entities that are closely linked to each other, by either direct link-ages or easily accessible entities that act as intermediates. The distributed community detection algorithm can find such community structures in a fully distributed opportunistic network.

Historical Background

At present, people widely use mobile devices to generate and consume digital media contents, producing large volumes of traffic. By 2020, the number of mobile users is expected to reach 70% of the global population (CISCO 2016). When there are no infrastructures and content providers in the network, mobile devices (nodes) can only communicate with each other via a wireless connection which may break suddenly, which is the Delay Tolerant Network (DTN). In DTN, nodes are strongly interdependent but human-centric because they contact with each other following the communication pattern of human beings, such as Mobile Social Network (MSN) and Pocket Switch Network (PSN). This phenomenon motivates researchers to borrow the concept of Social Network Analysis (SNA) to design useful schemes. As one of the most leveraged SNA, community detection is widely used.

A community is a set of nodes with a high density of internal links, whereas links between communities have comparatively lower density (Katsaros et al. 2010). In the research community, it is widely believed that identifying community information about recipients can help select suitable forwarders and reduce the delivery cost compared to naive oblivious flooding. It is a reasonable intuition because people in the same community are likely to meet each other regularly and to be appropriate forwarders of messages destined for other members in the community (Hui et al. 2007).

Inspired by the above standpoint, when the community structure is introduced into DTN, the following benefits can be found. On one hand,

with the community structures, a message is forwarded to the specific detected community and then to the destination node. It enhances the DTN routing effectiveness because the forwarding destination is extended as a group of nodes rather than just one destination node, which makes packet delivery be achieved easier and faster. On the other hand, social ties among community members are more entrenched than the social relationship between two nodes; therefore, the community-aware routing mechanism is relatively stable compared with routing without community structures.

In sociology, most community detection approaches are centralized, that is, the detection results are obtained based on the overall view of the network. However, in DTN, obtaining such an overall view of the network is unrealistic since nodes are fully distributed. Therefore, distributed community detection approaches should be designed. One of the famous community detections is the distributed k -clique community detection algorithm (Hui et al. 2007). A node records the encounter node as its community member if the latter has long encounter duration or many common friends with the former. The brief detection process is shown in Fig. 1 (Hui et al. 2007).

Firstly, each node (assume as v_0) needs to maintain the following information: a list of encountered nodes and the contact durations with each of them, the familiar set F_0 , the local community C_0 , and local approximation of the familiar sets of all nodes in its local community C_0 , which is denoted as $FSoLC_0$, that is

$$FSoLC_0 = \{\tilde{F}_j | v_j \in C_0, j \neq 0\} \quad (1)$$

Next, when v_0 encounters another v_i ($i \neq 0$), if v_i is not in F_0 and their total contact duration count exceeds a certain threshold, v_0 will insert v_i into F_0 and C_0 . If v_i is not in C_0 and F_i contains at least $k - 1$ members of C_0 , then v_0 adds v_i into C_0 . Besides, if $\tilde{F}_j$ contains at least $k - 1$ members of C_0 , v_j is added to the local community C_0 . Based on the simulation, it is observed that with a suitable threshold k , the k -clique can reach

Distributed Community Detection in Opportunistic Networks,
Fig. 1 The main principle of k -clique community detection (Hui et al. 2007)

around 80% of the performance of centralized algorithm.

Key Applications

MSN

MSN is a mobile communication system which involves social relationships of users. In such network, mobile users can access, share, and distribute data (e.g., video) in a mobile environment by exploiting their social relationships (Vastardis and Yang 2013). MSN has three architectures, i.e., the centralized one, the distributed one, and the hybrid one (Kayastha et al. 2011). In a distributed architecture, nodes connect with each other via the opportunistic encounters, which makes the communication mode become a DTN. Benefit from the detected community structures, MSN nodes are able to share their resources with the community members and route messages among each other more efficiently.

VANET

As a new technology that integrates the potentials of new-generation wireless networks into vehicles to enable communication among vehicles via Mobile Ad hoc Network (MANET) (Bonola et al. 2016), VANET (Vehicular Ad-hoc Network) is attractive to be integrated into smart cities. VANET is distinguished from other kinds of ad hoc networks due to its rapidly changing topology, large scale, and variable node

density. Generally, VANET can be classified into Vehicle-to-Infrastructure (V2I) and Vehicle-to-Vehicle (V2V); the former is the communication mode via infrastructures and the latter is that via vehicles only (Al-Sultan et al. 2014). VANET is a kind of DTN when it is established as the latter mode. Since VANET is formed by human-centric nodes (vehicles), community structures can also be employed to improve the VANET routing efficiency.

In-Network Caching

In-network caching allows nodes to cache the passed content locally. Thanks to the cached contents, forthcoming content requests can be responded in time. By detecting the community structures, user clusters are taken into account, which makes the network turn into some domains. It can improve the network scalability since nodes are autonomous, and a cluster head can be selected as the administrator to manage the community members, e.g., cache the popular data for the whole community. Therefore, the caching content of nodes can be rationally distributed.

Distributed IP Mobility Management

Carlos J. Bernardos

Universidad Carlos III de Madrid, Madrid, Spain

Synonyms

[Distributed anchoring](#); [DMM](#)

Definitions

Distributed IP Mobility Management (DMM) refers to the concept of placing mobility anchors closer to the user, distributing the control and data infrastructures among the entities located at the edge of the access network. This allows the mobile node's traffic to take an optimal route while enabling the mobile node move between mobility anchors. DMM appears as an alternative to classical centralized IP mobility management approaches, complementing them for better performance and scalability.

Motivation

Classical IP mobility management solutions, such as Mobile IPv6 (Perkins et al. 2011) or Proxy Mobile IPv6 (Gundavelli et al. 2008), require the presence of a central entity (home agent or local mobility anchor) that anchors the IP address used by the mobile node (MN). This centralized function is in charge of coordinating the mobility management. As a result, these centralized mobility anchors are burdened with data forwarding and control mechanisms for a huge number of users. While this centralized way of addressing mobility management has been fully developed by the Mobile IP protocol family and its many extensions, it brings several limitations that have been identified in Liu et al. (2015):

- Suboptimal routing: Since the (home) address used by an MN is anchored at the home link, traffic always traverses the central anchor, leading to paths that are, in general, longer than the direct one between the MN and its communication peer. This is exacerbated with the current trend in which content providers push their data to the edge of the network, as close as possible to the users, as, for example, deploying content delivery networks (CDNs). With centralized mobility management approaches, user traffic will always need to go first to the home network and then to the actual content source, sometimes adding unnecessary delay and wasting operator resources.
- Scalability problems: Existing mobile networks have to be dimensioned to support all the traffic traversing the central anchors. This poses several scalability and network design problems, as central mobility anchors need to have enough processing and routing capabilities to be able to deal with all the users' traffic simultaneously. Additionally, the entire operator's network needs to be dimensioned to be able to cope with all the users' traffic.
- Reliability: Centralized solutions share the problem of being more prone to reliability

problems, as the central entity is potentially a single point of failure.

In order to address these issues, distributed IP mobility management approaches are being explored and standardized by the DMM working group at the IETF.

DMM Solutions

There exist several approaches that can be followed to design a DMM solution. While no solution has been standardized so far (the IETF DMM WG is working on it), proposals span from extensions of current standardized protocols to clean-slate solutions. Next, the operation of two main families of DMM approaches is summarized.

Mobile IPv6-Based DMM Solution

Mobile IPv6 solutions, like Giust et al. (2015), are based on deploying multiple home agents at the edge of the network. Multiple of these anchors can be simultaneously used by a single MN. When a mobile node attaches to a distributed anchor router, it gets an IPv6 address which is topologically anchored at that router. While attached to this router, the mobile can send and receive traffic without traversing any tunneling nor special packet handling. If the MN moves and attaches to a different anchor router, it gets a new IPv6 address from that router. In case the MN wants to keep the reachability of the IPv6 address(es) it obtained from previous anchor (e.g., note that this decision is dynamic may be done on an application basis), the host has to involve its Mobile IPv6 stack, by sending a Binding Update to the router where the IPv6 address is anchored, using the address obtained from the current anchor as care-of address.

In this way, the IPv6 address that the node wants to maintain in use plays the role of home address, and the anchor from where that address was configured plays the role of home agent (for that particular address). In this scenario, old flows are anchored to the previously visited router, which is in charge to encapsulate the packets

and deliver them to the MN's care-of address (CoA). The IP tunnel is bi-directional, so the MN does the same when sending packets with the old address. Conversely, new IP flows are started using the address configured at the new anchor. These flows are handled by the new distributed anchor as a plain IPv6 router (see Fig. 1).

Proxy Mobile IPv6-Based DMM Solution

Proxy Mobile IPv6 solutions, like Giust et al. (2014), are based on replacing the role of the Mobile Access Gateway (MAG) by a new distributed anchor. This distributed anchor is provided with links to the Internet that do not imply paths traversing a Local Mobility Anchor (LMA). Hence, the distributed anchor acts as a plain access router (i.e., no tunneling) to forward packets to and from the Internet. Also, the distributed anchor features mobility anchoring functions, being able to forward without disruption the IP flows that an MN started while attached to it before moving to a new anchor afterward. The control plane functions of the LMA can be assumed by a control-only entity which stores, for every MN, all the

prefixes advertised to the MN, which anchor the MN is currently connected. This control plane entity is responsible of receiving/sending all the required mobility signaling (i.e., proxy binding updates and proxy binding acknowledgments) from/to the distributed anchors, so they can set up the required bi-directional tunnels to guarantee reachability of the addresses used by the MN, regardless of where these addresses are anchored (see Fig. 2).

Future Directions

DMM solutions are currently being standardized at the IETF. The 3GPP has also adopted distributed IP mobility management concepts in the 5G specifications of the cellular architecture (i.e., Release 15 and onward). In addition to the approaches described in this article, other solutions are also being explored, as the use of Segment Routing (Filsfilis and Previdi 2017), which might open the door for new ways of enabling network programmability.

Definitions

A distributed system divides end users' data into multiple segments. Each of partial nodes in the distributed system stores one or multiple data segments. However, the data segments stored in the distributed system may be tampered with by adversaries. Moreover, it is possible that the distributed system may discard some rarely accessed data segments to save the storage resource or alle-

viate some resource-constrained nodes' storage burden. Hence, the data storage security in the distributed system needs to be ensured.

Historical Background

The original intention of developing distributed computing is to use the idle computers to deal with other incidental computing tasks. Different from centralized computing, distributed computing can be used to process and store massive data with high efficiency and local resource saving. The first prototype of distributed computing was put forward by the Intel Corp at the end of the 1980s. With the explosive growth of Internet access terminals in the late 1990s and early twentieth century, the development of distributed computing technology has reached a climax. Currently, there are many information technologies developed by distributed computing, such as Mobile Agent technology, P2P technology, and Grid technology.

Cloud computing is a representative technology that is developed from distributed computing. Many distributed servers are connected together by the Internet in cloud computing. The cloud is managed by a cloud service provider (CSP). Users can enjoy the distributed storage services via the Internet. However, the data stored in the distributed servers may be tampered with and discarded by the CSP for financial reasons. According to a recent report by Twinstrata, only 50% of users choose the cloud to back up their data, and only 20% of them store their sensitive data in the cloud. Hence, how to protect the data in the distributed storage system is a serious issue that should be solved well. To avoid the data leakage, a cryptography method is used to encrypt the data before outsourcing it. A new emerging problem is how to verify the storage of the encrypted data in the distributed system.

Foundations

To ensure the distributed storage security, the system should allow users to check the integrity of

the stored data. Because users lose local control of their data after the data are outsourced to the remote distributed servers, they hope to check their stored data in the cloud at any time. In existing studies, there are three kinds of remote storage checking, which are described in the following.

- **Provable Data Possession (PDP)** PDP allows users to check whether their data stores in the remote server without retrieving all the data to the local side. The related studies can be found in Ateniese et al. (2007, 2008, 2011). Note that PDP is a probabilistic storage proof protocol. In other words, the user side can sample a random set of data segments and request the remote server to prove whether these data segments are stored in the corresponding server.
- **Proof of Retrievability (POR)** Similar to PDP, POR can also let users check the data possession in the remote server. Specially, POR protocols can allow users to check whether the data stored in the remote server can be retrieved to the local side (Juels and Kaliski 2007; Bowers et al. 2009; Dodis et al. 2009). In POR, a common approach is that the user generates authenticators for every data segments before data outsourcing. The authenticators can be used for the further verification of the data possession and retrievability.
- **Storage Auditing** In general, the data storage verification result may determine the reputation level of the remote storage server. If the data stored in one server is often destroyed, the number of users who choose to use the corresponding server to store their data will decrease. Moreover, the computational cost of data storage checking is also great. To alleviate the burden of the local user side and improve the fairness of the data storage checking, some researchers resorted to a TPA (third-party auditor) to design the data storage auditing protocols based on the homomorphic authenticator (Wang et al. 2010, 2013, 2011). In the storage auditing protocols, the user computes data tags and signatures for data segments and then outsources them with data segments to the server. Note that the TPA can

audit the data storage on behalf of the users without knowing the details of the stored data.

A comparison of the properties that the three protocols can provide is shown in Table 1.

Applications in Wireless Networks

Wireless terminals can communicate with each other via Wi-Fi or cellular network in wireless networks. Similar to the construction of the distributed system, end users can resort to neighboring wireless terminals to compute and store their data. Compared to nodes in the traditional distributed system, the wireless terminals have lower resource of the computing and the storage. Moreover, the information transmitted over wireless channels is more easily captured by attackers. Hence, the communication protocols in the wireless networks should be more secure, and more terminals need to be aggregated in the

wireless distributed system. A typical wireless distributed system is shown in Fig. 1. Note that there are many lightweight wireless devices in the wireless distributed system. These devices can communicate each other via wireless networks, and the aggregated data are forwarded to end users by remote wireless transmission infrastructures. Some applications of distributed data storage in wireless networks are listed in the following.

- *Secure distributed data storage for wireless networks* Wireless end users can eliminate the disadvantage of limited storage space by storing data segments in surrounding wireless terminals over wireless networks.
- *Secure distributed data computing for wireless networks* Wireless end users can delegate complex computing tasks to nearby wireless terminals whose computing capability is powerful than their own.
- *Secure distributed data sharing for wireless networks* Wireless terminals can transmit their own information to end users through wireless networks, and end users can also transmit their own data to any wireless terminal in the system through wireless networks.

Distributed Storage Security, Table 1 Properties of various data storage checking protocols

Properties	PDP	POR	Auditing
Publicly checking	N	N	Y
Local side checking	Y	Y	N

Batch verification	N	N	Y

Y: The protocol can provide the corresponding property
N: The protocol cannot provide the corresponding property
Y/N: The protocol cannot fully provide the corresponding property

Distributed Storage Security, Fig. 1 A typical distributed system for wireless networks

Future Directions

In the research of the distributed storage security, some future directions are summarized as follows.

- *More Efficient Data Dynamics* More efficient data dynamics implies that the distributed storage assurance protocols should support efficient data dynamics with low computational cost and high accuracy.
- *Data Deduplication* In a distributed storage system, it is possible that the same data block may be stored in two or more nodes, which wastes storage resource and may affect the verification of the data storage. Hence, it is necessary to propose some secure and effective data deduplication protocols for the distributed system.
- *Corrupted Data Location* In the batch verification of the data storage, the fail of the verification may be caused by one data segment or part of the data segments. Hence, a protocol that can locate the corrupted data segments in the batch storage verification needs to be proposed.

Targeted drug delivery

Definition

Drug delivery via nanomachines is one type of targeted drug delivery (TDD) technologies that delivers medicament to the designated area in vivo by using devices ranging in size from 0.1 to 10 μm and constructed of nanoscale components. Various terms such as nanomachine, nanorobot, nanobot, nanoid, nanite, and nanomite have been used to describe such devices. These nanomachines are loaded with drugs and targeted solely to diseased tissue under the manipulation and guidance of an external monitoring system. The purpose of this technology is to remarkably enhance locoregional therapies for disease treatment while reducing the side-effects of the drug on healthy cells.

Historical Background

In traditional drug delivery systems such as oral ingestion or intravascular injection, the medication is distributed throughout the body via the systemic blood circulation. For most therapeutic agents, only a small portion of the medication reaches the organ to be treated. Conventional chemotherapy shows that only a small fraction of drugs (0.1%) are taken up at the tumor cells,

whereas the remaining part (99.9%) are absorbed by healthy tissue (Trafton 2009).

On the other hand, TDD seeks to concentrate the medication in the site of interest while reducing the relative concentration of the medication in the remaining regions. For example, by avoiding the host's defense mechanisms and inhibiting nonspecific distribution in the liver and spleen (Bertrand and Leroux 2011), a system can reach the intended site of action in higher concentrations. This ability for drug molecules to concentrate in areas of diseased tissue is accomplished through three targeting mechanisms: passive, active, and physical. Passive targeting refers to producing a natural distribution difference of the drug in vivo by utilizing the specific physiological and structural characteristics of tissues and organs, thereby achieving a targeting effect. One example is the preferential accumulation of chemotherapeutic agents in solid tumors as a result of the difference in vascularization of tumor tissue compared with healthy tissue (Sagnella and Drummond 2012). Active targeting confers the drug an ability to actively bind to the target by attaching the probe molecules with chemical or physical methods, thereby enhancing the specificity of nanomachines to the targeted site. One example is to utilize cell-specific ligands that will allow for nanoparticles to bind specifically to cells that have the complementary receptor. Physical targeting uses physical signals such as light, heat, ultrasound, electric field, and magnetic field to artificially regulate the distribution and releasing of drugs in the body and achieve targeted delivery.

TDD via nanomachines is the technology that utilizes nanomachines to further improve its targeting efficiency. Similar to other research topics in nanotechnology, the origin of this technique comes from the Nobel Prize-winning theoretical physicist Richard Feynman, who first presented the idea of nanomachines in 1959. In his seminal speech "There's Plenty of Room at the Bottom" (Feynman 1992), Feynman envisioned that in the future humans might build a molecule-sized miniature machine to "arrange the atoms the way we want" and to perform chemical synthesis by mechanical manipulation. This led to the idea of

using nanorobots to treat diseases, which in Feynman's words is called "swallowing the doctor."

TDD via nanomachines relies heavily on the development of nanorobotic technologies. After decades of exploration, the research of manufacturing suitable nanorobots is mainly concentrated in two directions: (i) engineering the existing bacteria in nature with specific functions to create biological robots for drug delivery (Martel et al. 2009) and (ii) fabricating an artificial carrier with synthetic material that is harmless to the human body for drug delivery (Bae and Park 2011).

During the TDD process, there are several environmental uncertainties such as circulation and diffusion of nanomachines in the blood stream, which have a significant impact on the drug accumulation in the targeted site (Bae and Park 2011). In order to overcome these limitations and improve the transport efficiency, control strategies have been introduced to guide the movement of nanomachines (Liu et al. 2017; Guo et al. 2015). For instance, an optical-control mechanism proposed in Liu et al. (2017) generated dynamic tweezers to spin the nanomachines by a modified optical filter, which achieved bright and dark soliton conversion behaviors. Furthermore, a magnetic-control mechanism conveyed the device from one location to another along a predetermined path by utilizing the magnetic gradient propulsion. Another challenge during TDD is the biodegradability and biocompatibility of nanomachines. Injecting nanomachines into the human body for medical applications requires these devices to be biologically harmless, where the drug concentration should not reach toxic levels (Bae and Park 2011).

Communication models and theories have been applied to optimize TDD by modelling the procedure as an information sending and receiving process, where drug nanoparticles are information molecules through which messages are encoded, and injection and delivery of drugs correspond to the transmitting and receiving processes (Chahibi et al. 2015a; Chen et al. 2017a). This approach transforms TDD by applying performance measures traditionally only known to the communi-

cations community to rigorously define the efficiency of TDD. Furthermore, it allows for the utilization of classical communications techniques and protocols to design optimally targeted therapies. While most of the works do not consider utilizing externally controllable nanocarriers for TDD, Chen et al. (2017a) focus on the scenario of nanorobots-assisted TDD. Communications-inspired TDD via nanomachines has been incorporated in the first IEEE Standard on Nanoscale and Molecular Communications 1906.1 as a use case (IEEE NanoCom Standards Development Working Group 2017).

Foundations

Engineered bacterial nanomachines: The most widely considered bacterial nanomachines are the magnetotactic bacteria (MTB) with flagellated nanomotors combined with the nanometer-sized magnetosomes as a means of propulsion or bio-actuation (Martel et al. 2009). MTB synthesize intracellular Fe_3O_4 nanoparticles, called magnetosomes, assembled in a chain acting as a compass to guide their movement following the applied magnetic field. Engineered bacterial nanomachines have a size varying in the range of 0.5–3 μm (Martel et al. 2009). The advantage of using bacterial nanomachines is to avoid the difficulty of developing an autonomous (i.e., without the need for an external power source for propulsion) engine capable of sufficient thrust for practical applications. A swarm of MTB can be used to push, transport, and manipulate a microobject with precise control over their displacement (Martel et al. 2009). In addition to MTB, there are other bacterial materials that can be used to manufacture bio-nanomachines, such as cellulosome which are a complex of multicellulolytic enzymes that dismantle plant polysaccharides (Artzi et al. 2017).

Artificial nanomachines: The most commonly considered artificial nanomachines are built upon chemically synthesized simple geometric structures such as helical, tubular, and capsule shapes (Chen et al. 2017b). Due to the limitation

in fabrication, at present it is difficult to embed on-board power sources within these nanomachines; therefore, the magnetic field is also widely used for their actuation and control. However, unlike MTB which utilize their flagellated nanomotors to move forward, artificial nanomachines obtain their forward momentum under the influence of a magnetic field via spin. For instance, once a nanomachine is placed inside a uniform magnetic field generated by an approximate Helmholtz electromagnetic coil system, the magnetic field creates a torque on the nanomachine, causing it to rotate. Subsequently, the nanomachine maintains its movement as it heads towards the coil with its original orientation (Kim et al. 2016). Most nanomachines under development have characteristic lengths in the order of $1\text{ }\mu\text{m}$ to $100\text{ }\mu\text{m}$ and are fabricated using a wide variety of techniques including direct laser writing, templated directed electrodeposition, self-scrolling, shadow-growth, microfabrication, underpotential deposition, to name a few (Kim et al. 2016).

Drug loading and releasing: Before being injected into the human body, drug molecules are attached to the surface of a nanomachine by chemical bonding (Hu et al. 2014) or are encapsulated inside a nanomachine (Chen et al. 2017b). Drug releasing in vivo is a very challenging task. A common strategy is to use external stimuli to make the outer package degrade and cause the release of the encapsulated drug. Such stimuli include pH, temperature, light, ultrasound, magnetic field, and enzymes. For instance, when a magnetic liposome is applied to nanomachine manufacturing, it will incorporate degradable polymers, which can degenerate under an external stimulus and release the drug at a specified time (Chude-Okonkwo et al. 2016). Another example is to utilize oxidoreductases as a gate in the responsive controlled release system. Glucose oxidase is extensively used as a diagnostic tool in the detection of glucose values. Upon addition of the hyperglycemic state, glucose oxidase encapsulated in the nanomachine begin converting glucose into gluconic acid, resulting in dissociation of the package and subsequent release of insulin (Hu et al. 2014).

Controlling mechanism: Major advances have been achieved to control the motion of nanomachines to steer them towards desired sites by inducing external gradients. These stimuli are categorized as chemical, optical, ultrasonic, electric, and magnetic.

Chemical stimuli can trigger swarming behavior of different types of catalytic nanomachines ranging from simple to more complex units such as Janus spheres and Au nanowires. For instance, chemically induced aggregate behavior has been observed in self-propelled Au nanoparticles. The process contains chemical reaction between hydrazine and H_2O_2 catalyzed by the gold surface that generates chemical gradients on the nearby Au nanoparticles, which pull the particles towards the center of the swarms where the largest electrolyte gradient existed (Liu et al. 2017). However, for chemically triggered swarming behavior, the swarming time is highly dependent on the reaction speed, which limits its applications.

Optical stimuli have also been an efficient method for inducing aggregation of nanomachines. This mechanism is defined as the use of intensely focused light beams to accurately trap and manipulate nanomachines. Intensity gradients generated by a converging beam are able to polarize nanomachines to move towards the highest gradient region of the electric field (Liu et al. 2017).

Another effective way to regulate the collective behavior of nanomachines is ultrasound, which is an on-demand motion control, long lifetime, and noninvasive aggregation method. Interactions between ultrasound and nanomachines lead to swarming phenomena based on pressure nodes or antinodes, where the nanomachines migrate from peaks and accumulate in the troughs of the associated standing waves (Guo et al. 2015).

Electric stimuli induce dielectrophoresis, which is a phenomenon exerted on dielectric nanomachines suspended in water solution to initiate the gathering of nanomachines (Liu et al. 2017). The application of this method to TDD has been limited because it requires complex configuration to generate appropriate

field and high voltages that may damage tissue.

Magnetic stimuli are the most common way to remotely control the motion of nanomachines. Magnetic fields can be used to manipulate the motion of nanomachines as well as track their movement. This stimulus also has the capability of superfast operation as its response time is just a few seconds. Injected nanomachines loaded with drug molecules can be aggregated and guided by a local magnetic field, which can be applied in nearly all human tissues without any toxicity (Liu et al. 2017). Table 1 gives a comparison between several different types of nanomachines and their control mechanisms.

Communication-inspired system design: The molecular communication (MC) models can be applied to describe the TDD process (Chahibi et al. 2015a; Chen et al. 2017a). In MC, an engineered miniature transmitter emits molecules, which propagate and are eventually received by a miniature receiver. The information may be encoded in either the timing or the concentration of molecules. The reception process often involves a chemical reaction between molecules (ligand) and compliant receptors present on the receiver surface.

Under this framework, the drug nanoparticles are the information molecules through which messages are encoded, the injection and delivery of the therapeutic agent correspond to the transmission and reception of signals, and the blood vessels responsible for the transport of the drug are the communication channel. The signal is the concentration-time profile of the therapeutic agent, which should be successfully received by the tumor to decrease its size. Figure 1 provides general molecular communication system models with and without external controlling factor.

This analogy enables the analysis and design of TDD by utilizing performance measures traditionally only used in the communication field. By applying the queuing theory to model receptor saturation, thus treating it as a congestion problem in communication networks, the optimal drug release rate was estimated in Femminella et al. (2015) to guarantee that the desired fraction of receptors bound to drug molecules without drug over loading. By modeling the pharmacokinetics of TDD systems as the channel impulse response in communication systems, the optimal drug injection rate was obtained in (Chahibi et al. 2015a). By applying the antibody-mediated TDD system transport and antigen-binding kinetics and taking into account the geometry of the antibody molecule, the electrochemical structure of the antibody-antigen complex, and the physiology of the patient, optimal shape of the antibody molecular structure was determined in (Chahibi et al. 2015b). By using contrast-enhanced microwave imaging as a pretherapeutic evaluation technique to determine the pharmacokinetic model of nanorobots-assisted TDD, strategies for optimal targeted therapies were presented from the communication waveform design perspective (Chen et al. 2017a).

Vascular network channel model: Due to the limitations of modern medical imaging technologies, it is difficult to obtain the exact values of all important vascular parameters such as topology, size, orientation, speed of blood flow. Thus, in order to analyze the pharmacokinetics of TDD systems through the abstraction of MC, it is necessary to utilize statistical approaches to simulate the vascular morphology. The fractal model is often chosen as the first approximation because the distributive function of vasculature is to bring

Drug Delivery via Nanomachines, Table 1 Several types of nanomachines and corresponding control mechanisms

Type	Controlling mechanism	Propulsion
Magnetotactic bacteria	Magnetic field	Flagella

Drug Delivery via Nanomachines, Fig. 1 Communications-inspired drug delivery system model: (a) without an external controlling unit and (b) with a controlling unit

a stream of blood to every living cell within the body or organ and is achieved by successive dichotomous division, or bifurcation. The self-similarity of bifurcation at each node gives the vascular connection a fractal character. In Chen et al. (2017a), a fractal-based model is proposed to consider the random realization of a single propagation path on the fractal tree from the transmitter (injection site) to the receiver (cancer cells). Another similar model in Chahibi et al. (2015a) introduces an interesting method that maps the cardiovascular network into an equivalent circuit. Meanwhile, a more detailed model based on Chen et al. (2017a) is presented in Zhou et al. (2018) to explore the properties of the grid-like region near the tumor site.

Key Applications

Drug delivery via nanomachines is the most promising solution for TDD. Drug-loaded nanomachines are notably utilized in different environments and operations relevant to the treatment and prevention of diseases such as metabolic disorders, inflammatory diseases, autoimmune diseases, neurodegenerative diseases, and cancer. Among them, the application of cancer treatment has drawn the most attention. The pain caused by conventional cancer treatments such as chemotherapy that are often accompanied by huge side effects is not even better than the pain caused by cancer itself. Most of the drugs applied in the treatment of cancer

have a certain toxicity (Bae and Park 2011). This toxicity not only kills healthy cells but also affects the size of the therapeutic window (low drug concentration is difficult to produce a therapeutic effect while the high concentration is easy to produce intolerable toxicity). TDD system based on nanomachines can perform a dual effect that expands the therapeutic window to achieve greater drug efficacy while being less prone to toxicity and reducing the accumulation of drugs in nontarget sites (Bertrand and Leroux 2011; Bae and Park 2011).

Furthermore, drug-loaded nanomachines are gaining increasing attention in the application of overcoming multidrug resistance in cancer therapy. Nanomachines between 10 and 200 nm exhibit prolonged systemic circulation lifetime, sustained drug release kinetics, and better tumor accumulations through both passive and active mechanisms. Those features provide the ability to co-encapsulate multiple therapeutic agents and to synchronize their delivery to the diseased cells (Gao et al. 2012).

Future Directions

Research on TDD systems is still in its infancy. A great deal of efforts is demanded in the areas of nanomachine manufacturing and controlling, drug loading and releasing, and communications-inspired optimal TDD. The existing nanorobotic technologies can hardly satisfy the requirements of controlled directional movement, drug molecules' transportation and releasing, biocompatibility and biodegradability, etc., at the same time. There is still a long way to go before reaching the ultimate goal of clinical applications. Various control methods also have deficiencies in the surveillance and positioning of nanorobots in the human body, especially in the capillary-level microenvironment. As a result, the communications-inspired design of TDD via nanomachines has to make substantial assumptions about the system and channel models for the motion analysis and parameter optimization. These problems will need to be gradually resolved with further experimental verification.

Dynamic Pricing

Dusit Niyato
School of Computer Science and Engineering
(SCSE), Nanyang Technological University
(NTU), Singapore, Singapore

Definitions

Dynamic pricing is a mechanism in which the price is determined dynamically and iteratively through dynamic algorithms. The algorithms can yield optimal or equilibrium pricing solutions that maximize the profit of a single monopolistic seller or multiple oligopolistic sellers, respectively.

Economic Modeling and Pricing

Economic and pricing approaches have been applied to address many issues in wireless/radio resource management. In the following, major economic and pricing models used in the wireless literature are presented Luong et al. (2017).

Cost-based pricing: Cost-based pricing is a common pricing strategy to determine the price of wireless resource and service based on calculating the total cost of acquiring the resource and offering the service as well as adding a percentage of the cost as a desired profit. The goal of cost-based pricing is to ensure that the price yields nonnegative profit to the wireless service provider profitable. The total cost generally consists of a fixed cost and a variable cost. The fixed cost is the cost that does not change when the number of sales of the services changes, for example, hardware costs, for example, servers and network devices, and installation. On the contrary, the variable cost incurs depending to the number of product produced or the amount of services used. For example, the resource costs, for example, energy and bandwidth costs. The advantage of the cost-based pricing is the ease of setting the price. The reason is that the price is a function of the internal cost, i.e., the cost required to generate the service Courcoubetis and Weber (2003). However, this pricing strategy does not consider external market factors, for example, the pricing strategies of other providers and the perceive value and willingness to pay of buyers or users.

Differential pricing: The cost-based pricing ignores the requirement and preference of each user. On the other hand, to maximize the profit of providers, differential pricing, also called price discrimination, can be used, utilizing such user's requirement and preference. In the differential pricing, the provider can charge different prices to different users based on their demand and willingness to pay. By setting higher prices for one type of user, the use of the differential pricing explores the user surplus by the provider. However, it can be unfair to cause one type of users to pay a higher price than that of other types of user.

Profit maximization: Profit maximization is the process of determining the output quantity and/or the price that offer the highest profit for a provider Korrapati (2014). The pricing based on profit maximization concept is described in the following. Assume that a service provider needs to determine the amount of radio resource or wireless service units to be sold which is denoted by q and the price p for their users. The profit of the provider is $\pi = R(p, q) - C(q)$, where $R(\cdot, \cdot)$ is the total revenue and $C(\cdot)$ is the total cost. The total cost includes a fixed cost and a variable cost. The revenue is the amount of money that the provider receives from selling q resource units to its users. The optimal quantity of radio resource units, i.e., q^* , is determined such that the profit is maximized, i.e., $q^* = \max_q \pi$. The optimal quantity allows to find the optimal price based on the demand curve. The demand curve is typically a linear curve to show the relationship between the price of a resource unit and the quantity of resource units that users are willing to buy. A general demand curve can be expressed as $p = a - bq$, where a and b are proper parameters. Thus, at $q = q^*$, the optimal price is $p^* = a - bq^*$.

Game Theoretic Pricing

Game theory is the study of multiparticipant decision-making problems in which a choice of a participant, i.e., a player, potentially affects the interests of other participants Gibbons (1992). In the following, game theoretic models are briefly reviewed. Some important terminologies are defined below Shi et al. (2012).

- **Player:** A player is a participant which makes a decision in the game.
- **Payoff:** A payoff, i.e., a utility, a profit, or an interest, reflects the desired outcome of the player.
- **Strategy:** Player's strategy is a set of actions/instructions that the player can follow to achieve the desired outcome. The payoff is a function of not only the player's own action, but also the actions of others.

- **Rationality:** A player is rational if its strategy always aims at maximizing its own payoff.

Noncooperative game: In a noncooperative game, each player maximizes only its own payoff without considering the payoff of the other players nor the social welfare of the networks AlSkaif et al. (2015). In this game, the players are self-interested, and they do not form coalitions or make agreements with each other.

Consider a radio resource market in which providers as the sellers compete for selling radio resource units, for example, spectrum, to users. The sellers are typically selfish. As such, the market consisting of the providers selling the spectrum can be modeled as a non-cooperative game. The providers can adjust prices of the spectrum and therefore the prices are the strategies. Assume that there are N players, and P_i is a set of pricing strategies of player i , where $P = P_1 \times \dots \times P_N$. $\times$ is the Cartesian product of the sets of strategies of each player. Let $p_i \in P_i$ be the pricing strategy of player i . A vector of strategies of N players is $\mathbf{p} = (p_1, \dots, p_N)$, and a vector of corresponding payoffs is $\pi = (\pi_1(\mathbf{p}), \dots, \pi_N(\mathbf{p}))$, where $\pi_i(\mathbf{p})$ is the payoff of player i given the player's chosen strategy and strategies of all the other players. Each player optimizes its best strategy p_i^* which maximizes its payoff. A set of strategies $\mathbf{p}^* = (p_1^*, \dots, p_N^*) \in P$ is the Nash equilibrium of the noncooperative game if no player can gain higher payoff by changing its own strategy when the strategies of the others remain the same Friedman (1988), i.e.,

$$\forall i, p_i \in P_i : \pi_i(p_i^*, \bar{\mathbf{p}}_i^*) \geq \pi_i(p_i, \bar{\mathbf{p}}_i^*), \quad (1)$$

where $\bar{\mathbf{p}}_i = (p_1, \dots, p_{i-1}, p_{i+1}, \dots, p_N)$ is a vector of prices of all players except player i .

Stackelberg game: The noncooperative game assumes that players chooses and releases their pricing strategies simultaneously. Also, all the players know each other's strategies at the same time. However, this may not always hold in real markets. Therefore, sequential games can be used

in which players can choose and release their strategies following a certain predefined order. This situation can be modeled as a Stackelberg game Amir and Grilo (1999). In the Stackelberg game, the players are divided into leaders and followers. The follower players decide its own strategic choices after observing the strategies of leader players Kim (2014). It was proved that even if the leader players can choose their strategies first, their payoffs are not less than those at the Nash equilibrium Han (2012), i.e., because of the first-mover advantage. The following provides the definition and properties of the Stackelberg game. Assume that there are two radio resource sellers 1 and 2 in the market. P_1 and P_2 are the sets of pricing strategies of sellers 1 and 2, respectively. Seller 1 chooses its pricing strategy p_1 from set P_1 to maximize its payoff or profit function $\pi_1(p_1, p_2)$, and seller 2 chooses its pricing strategy p_2 from set P_2 to maximize its payoff function $\pi_2(p_1, p_2)$. Also, assume that seller 2 selects its strategy before seller 1 decides its selection, and hence seller 1 is able to observe the strategy of seller 2. Seller 2 is then the leader, and seller 1 is the follower. We have the following definition Leitmann (2013):

Definition 1

If there exists a mapping $F : P_2 \rightarrow P_1$ such that, for any fixed $p_2 \in P_2$, $\pi_1(F(p_2), p_2) \geq \pi_1(p_1, p_2)$, $\forall p_1 \in P_1$, and if there exists $p_{2s2} \in P_2$ such that $\pi_2(F(p_{2s2}), p_{2s2}) \geq \pi_2(F(p_2), p_2)$, then the pair $(p_{1s2}, p_{2s2}) \in P_1 \times P_2$, where $p_{1s2} = F(p_{2s2})$, is called a Stackelberg strategy pair.

Definition 1 presents that the Stackelberg strategy is optimal for the leader when the follower responds to the leader with the follower's optimal strategy.

Case Study of Dynamic Spectrum Pricing

Pricing Models

Market-Equilibrium-Based Pricing: In the market-equilibrium pricing model, the primary service is not aware of other primary services.

Thus, at the seller side, the primary service naively sets the price according to the spectrum demand of the secondary service. This price setting is based on the willingness of the primary service to sell spectrum which is generally determined by the *supply function*. For a given price, supply function indicates the size of radio spectrum to be shared by a primary service with the secondary service. At the buyer side, the willingness of a secondary service to buy spectrum is determined by the *demand function*. Again, for a given price, demand function determines the size of radio spectrum required by a secondary service. In this spectrum trading, market-equilibrium price denotes the price for which spectrum supplied by the primary service is equal to the spectrum demand from the secondary service. This market-equilibrium price ensures that there is no excess supply in the market and spectrum supply meets all spectrum demand.

Competitive Pricing: In the competitive pricing model, a primary service is aware of the existence of other primary services and all of the primary services compete with each other to achieve the highest individual profit. The competition here occurs in terms of spectrum pricing. In particular, given the spectrum prices offered by other primary services, one primary service chooses the price for its own spectrum so that its individual profit is maximized. This competitive spectrum pricing can be considered as a price war in an oligopoly market. In this market structure, the firms choose their price noncooperatively. The decision of each seller is influenced by other sellers' actions and action of one seller may be observed by other sellers. A general description for this oligopoly market is as follows. There are N sellers, i.e., primary services, in the market offering the same or differentiated product, i.e., spectrum. The seller competes with each other by adjusting the price of product selling to the buyer, i.e., secondary service. In this competitive situation, when one seller varies the price, demand for that product will change and other sellers will observe and adjust their prices to gain higher profit. This competition in oligopoly market can be modeled by noncooperative game.

Cooperative Pricing: In the cooperative pricing model, it is assumed that all of the primary services know each other and they fully cooperate (i.e., collude) to obtain the highest total profit by selling spectrum to the secondary service. In an actual environment, to achieve this full cooperation, extensive communication would be required among all primary services. The demand function for spectrum F_i at the secondary service can be obtained using $\frac{\partial U(\mathbf{b})}{\partial b_i} = 0$ as:

$$D_i(\mathbf{p}) = \frac{(k_i^{(s)} - p_i)(v(N-2)+1) - v \sum_{i \neq j} (k_j^{(s)} - p_j)}{(1-v)(v(N-1)+1)},$$

where $\mathbf{p}$ denotes a vector of prices offered by all primary services in the market (i.e., $\mathbf{p} = [p_1 \dots p_i \dots p_N]^T$).

Revenue and Cost Functions for a Primary Service: For a primary service, there are two sources of revenue – from primary users and secondary users. However, a cost is involved which is a function of QoS performance degradation of ongoing primary users due to sharing the radio spectrum with secondary service. We assume that the primary users are charged at a flat rate for a guaranteed amount of bandwidth. However, if the required bandwidth cannot be provided, a primary service offers “discount” to the users, and this is considered as the cost of sharing spectrum with the secondary service. Let R_i^l denote the revenue gained from primary users served by primary service i , R_i^s denote the revenue gained from sharing spectrum with secondary users, and C_i denote the cost due to QoS degradation of primary users. Then, the revenue and cost functions can be defined as: $R_i^s = p_i b_i$, $R_i^l = c_1 M_i$, $C_i(b_i) = c_2 M_i \left(B_i^{req} - k_i^{(p)} \frac{W_i - b_i}{M_i} \right)^2$, where b_i and p_i denote, respectively, the spectrum size shared with secondary service and the corresponding price, and c_1 and c_2 denote constant weights for the revenue and cost functions at the primary service, respectively. Here, B_i^{req} denotes bandwidth requirement per user, W_i denotes spectrum size, M_i denotes the number of ongoing primary users, and $k_i^{(p)}$ denotes spectral efficiency of wireless transmission for primary service i . Note that revenue from the primary users is a linear function of the number of

concurrent users, while revenue from secondary users is a linear function of the shared spectrum size given the spectrum price. The cost is proportional to the square of the difference between bandwidth requirement and allocated bandwidth to a primary user.

Solution of Pricing Models

Solution of Market-Equilibrium Pricing Model:

For each primary service, the spectrum supply function can be derived based on a profit maximization problem. The solution of this optimization formulation is the optimal spectrum size b_i to be shared with the secondary service for a given price p_i . Based on revenue (i.e., R_i^l and R_i^s) and cost (i.e., C_i), profit P_i of a particular primary service i owning spectrum F_i can be expressed as: $P_i = p_i b_i + c_1 M_i - c_2 M_i \left(B_i^{req} - k_i^{(p)} \frac{W_i - b_i}{M_i} \right)^2$. To obtain the optimal spectrum size to be shared, we differentiate the profit function with respect to b_i (when p_i is given) and obtain that $\frac{\partial P_i}{\partial b_i} = 0 = -p_i + 2c_2 M_i \left(B_i^{req} - k_i^{(p)} \frac{W_i - b_i}{M_i} \right) \frac{k_i^{(p)}}{M_i}$.

Spectrum supply is given by the optimal value of b_i^* which is a function of price p_i . The supply function can be expressed as: $S_i(p_i) = W_i - \frac{M_i}{k_i^{(p)}} \left(B_i^{req} - \frac{p_i}{2c_2 k_i^{(p)}} \right)$. The market-equilibrium (i.e., solution) is defined as the price p_i^* at which spectrum supply equals spectrum demand, i.e., $S_i(p_i^*) = D_i(\mathbf{p}^*)$, $\forall i$, where the vector $\mathbf{p}^* = [\dots p_i^* \dots]^T$ denotes the market-equilibrium prices for all primary services.

Solution of Competitive Pricing Model: We use a noncooperative game to model the price competition among primary services. The players (i.e., sellers in an oligopoly market) in this game are the primary services. The strategy of each of the players is the price per unit of spectrum. The payoff for each primary service i (denoted by P_i) is the individual profit due to selling spectrum to the secondary service.

Again, based on the demand, revenue, and cost functions, the individual profit of each primary service can be expressed as follows: $P_i(\mathbf{p}) =$

$R_i^s + R_i^l - C_i$, where $\mathbf{p}$ denotes a vector of prices offered by all of the players (i.e., primary services) in the game. We consider the Nash equilibrium as a solution of this price competition. In this case, the Nash equilibrium is obtained by using the best response function which is the best strategy of one player given others' strategies. The best response function of primary service i , given a vector of prices offered by other primary services $\mathbf{p}_{-i}$, is defined as: $B_i(\mathbf{p}_{-i}) = \arg \max_{p_i} P_i(p_i, \mathbf{p}_{-i})$.

The vector $\mathbf{p}^* = [\dots p_i^* \dots]^T$ denotes a Nash equilibrium (i.e., solution) of this game on competitive pricing if and only if $p_i^* = B_i(\mathbf{p}_{-i}^*) \forall i$, where $\mathbf{p}_{-i}^*$ denotes the vector of best responses for player j for $j \neq i$. Mathematically, to obtain the Nash equilibrium, we have to solve the following set of equations: $\frac{\partial P_i(\mathbf{p})}{\partial p_i} = 0$ for all i . In this case, the size of the shared bandwidth b_i in the individual profit function is replaced with spectrum demand $D_i(\mathbf{p})$, and then the profit function can be expressed as: $P_i(\mathbf{p}) = p_i D_i(\mathbf{p}) + c_1 M_i - c_2 M_i \left(B_i^{req} - k_i^{(p)} \frac{W_i - D_i(\mathbf{p})}{M_i} \right)^2$.

Then, using $\frac{\partial P_i(\mathbf{p})}{\partial p_i} = 0$, we obtain that $2c_2 k_i^{(p)} D_2 \left(B_i^{req} - k_i^{(p)} \frac{W_i - (D_1(\mathbf{p}_{-i}) - D_2 p_i)}{M_i} \right) + D_1(\mathbf{p}_{-i}) - 2D_2 p_i = 0$. Recall that the demand function can be expressed as $D_1(\mathbf{p}) = D_1(\mathbf{p}_{-i}) - D_2 p_i$. The solution p_i^* , which is a Nash equilibrium, can be obtained by solving the above set of linear equations by using a numerical method when all the above parameters are available. Then, given a vector of prices $\mathbf{p}^*$ at the Nash equilibrium, the size of the shared spectrum can be obtained from the spectrum demand function $D_i(\mathbf{p}^*)$.

Solution of Cooperative Pricing Model: For the cooperative pricing model, an optimization problem is formulated to obtain the optimal price which provides the highest total profit for all primary services. This optimization problem can be expressed as follows:

$$\text{Maximize : } \sum_{i=1}^N P_i(\mathbf{p}), \quad (2)$$

$$\text{Subject to : } W_i \geq b_i \geq 0, \quad (3)$$

$$p_i \geq 0, \quad (4)$$

where the total profit for all the primary services is given by $\sum_{i=1}^N P_i(\mathbf{p})$. Since the constraint in Eq. (3) can be written as $W_i \geq D(\mathbf{p}) \geq 0$, the Lagrangian can be expressed as: $L(\mathbf{p}) = \sum_{i=1}^N P_i(\mathbf{p}) - \sum_{j=1}^N \lambda_j (-p_j) - \sum_{k=1}^N \mu_k (D_k(\mathbf{p}) - W_k) - \sum_{l=1}^N \sigma_l (-D_l(\mathbf{p}))$, where λ_j , μ_k , and σ_l are Lagrange multipliers for the constraints in Eqs. (3) and (4), respectively. Using Kuhn-Tucker conditions, we can obtain the vector of optimal prices $\mathbf{p}^*$ such that the total profit of all the primary services is maximized.

Dynamic Pricing Algorithms

In a practical cognitive radio environment, a primary service may not have the complete network information. Therefore, the primary service must learn the behavior of other entities from the history, and a distributed price adjustment algorithm is required which would gradually reach the solution.

Distributed Implementation of Market-Equilibrium Dynamic Pricing: The solution of this pricing model is given by market-equilibrium which is defined as the price at which spectrum supply from a primary service is equal to spectrum demand from the secondary service. Therefore, the price offered by each primary service is gradually adjusted in a direction that minimizes the difference between spectrum demand and supply. This process works as follows. The spectrum price is initialized to $p_i[0]$ and this price is sent to the secondary service. The secondary service replies with the size of spectrum demand which is computed from the demand function $D_i(\mathbf{p}[t])$ for spectrum F_i . Then, the primary service computes the size of the supplied spectrum $S_i(p_i[t])$. To obtain the price in the next iteration, the difference between spectrum demand and supply at time t is computed, weighted by learning rate α_i , and added to the price in the current iteration. This process repeats until the difference of prices in current iteration t

and next iteration $t + 1$ becomes less than the threshold ε (e.g., $\varepsilon = 10^{-5}$). This price adjustment in each iteration can be expressed as: $p_i[t + 1] = p_i[t] + \alpha_i(D_i(\mathbf{p}[t]) - S_i(p_i[t]))$, where $\mathbf{p}[t]$ is the vector of prices at iteration t , i.e., $\mathbf{p}[t] = [p_1[t] \cdots p_i[t] \cdots p_N[t]]^T$.

Distributed Implementation of Competitive Dynamic Pricing: The solution of this dynamic pricing model is given by the Nash equilibrium. It is defined as the prices which satisfies all of the primary services. We assume that a primary service cannot observe the prices of other primary services. Therefore, each primary service can use only local information and spectrum demand information from the secondary service to adjust its strategy. This distributed competitive dynamic pricing works as follows. The spectrum price is initialized to $p_i[0]$ and this price is sent to the secondary service. The secondary service replies with the size of spectrum demand. Also, the primary service estimates marginal individual profit and uses this together with spectrum demand information to compute the spectrum price in the next iteration. The relationship between the prices in the current and the next iterations can be expressed as: $p_i[t + 1] = p_i[t] + \alpha_i \left(\frac{\partial P_i(\mathbf{p}[t])}{\partial p_i[t]} \right)$, where α_i is the learning rate. Let $\mathbf{p}_{-i}[t]$ denote the vector of prices of all primary services except service i at iteration t . To estimate the marginal individual profit, a primary service can observe the marginal spectrum demand for a small variation in price ξ (e.g., $\xi = 10^{-4}$). That is,

$$\frac{\partial P_i(\mathbf{p}[t])}{\partial p_i[t]} \approx \frac{P_i([\cdots p_i[t] + \xi \cdots]) - P_i([\cdots p_i[t] - \xi \cdots])}{2\xi} \quad (5)$$

Note that due to this estimation of marginal individual profit, communication overhead between a primary service and the secondary service is larger than that in case of market-equilibrium dynamic pricing model. Nonetheless, communication among primary services is not required for distributed competitive dynamic pricing algorithm.

Distributed Implementation of Cooperative Dynamic Pricing: The solution of this dynamic pricing model yields an optimal price for which the total profit of all primary services is maximized. Again, we assume that a primary service can observe the variation of spectrum demand from the secondary service. In addition, to achieve the highest total profit, primary services can exchange information on current profit among each other. This is possible only if all the primary services are fully cooperative. The distributed cooperative dynamic pricing then works as follows. The spectrum price is initialized to $p_i[0]$ and then it is sent to the secondary service. The secondary service replies with the spectrum demand. Then, the primary service estimates marginal total profit by exchanging information with the other primary services and uses this together with the spectrum demand from secondary service to compute spectrum price in the next iteration. The price update is done as: $p_i[t + 1] = p_i[t] + \alpha_i \left(\frac{\partial \sum_{j=1}^N P_j(\mathbf{p}[t])}{\partial p_i[t]} \right)$. Again, similar to that in Eq. (5), to estimate marginal total profit, a primary service can observe the marginal total profit through information exchange among all primary services for a small variation in price ξ as:

$$\frac{\partial \sum_{j=1}^N P_j(\mathbf{p}[t])}{\partial p_i[t]} \approx \frac{\sum_{j=1}^N P_j([\cdots p_i[t] + \xi \cdots]) - \sum_{j=1}^N P_j([\cdots p_i[t] - \xi \cdots])}{2\xi}$$

Compared with the market-equilibrium and competitive dynamic pricing models, this estimation of marginal total profit incurs the largest

communication overhead since the profit information needs to be exchanged among all the primary services.

Dynamic Spectrum Access in Multiple Primary Networks

Ye Wang and Yi Yang
Harbin Institute of Technology (Shenzhen),
Shenzhen, China

Cognitive radio technology is an effective way to solve the contradiction between the rapid devel-

opment of wireless applications and inefficient spectrum allocation. However, the preemptive priority of the primary users (PUs) and the space time variation characteristics of the idle channel lead to the unstable performance of the cognitive radio network (CRN). With the development of network convergence technology and the popularity of heterogeneous networks, the cognitive radio network with multiple primary networks (CRNMPNS) is becoming possible. CRNMPNS provides more spectrum resources and network selections.

Network Topology

Multiple primary cognitive radio networks consist of PRNs (primary radio networks) and CRNs (cognitive radio networks). Its topological structure is shown in Fig. 1. Some PRNs are distributed in a certain geographical area, and CRNs are located in the area around them.

CRN consists of SUs and Fusion Center (FC). SUs are divided into in-band SUs and out-of-band SUs. In-band SUs refer to SUs that have access to authorized channels, and those that have not access are called out-of-band SUs. For in-band SUs, it is not necessary to participate in spectrum sensing all the time. It is only necessary to periodically sense whether the currently occupied channel has a PU's arrival while maintaining normal communication. If a PU arrives, it immediately exits the current channel and sends access request to FC again. For out-of-band SUs, FC allocates spectrum sensing. If there is an idle channel, FC allocates the right to access the authorized channel. Because FC has known the distribution of in-band SUs, the sensing channel only includes the channel occupied by PU and idle channel.

The workflow diagram of multiple primary cognitive radio networks is shown in Fig. 2. Firstly, according to the current network state, FC adopts a certain cooperative sensing scheduling scheme. According to the sensing scheduling, SUs sense the corresponding PRNs. Then, SUs are sensed separately by single-point sensing, and the sensing results are fused by FC according to

Dynamic Spectrum Access in Multiple Primary Networks, Fig. 1 Topological structure of CRNMPNS

certain fusion criteria to determine the current final channel state of PRNs. When SU initiates an access request, FC chooses the best PRN for dynamic spectrum access according to the corresponding network selection scheme. Finally, the performance of the CRN network is evaluated, such as PU collision probability, CRN throughput, SU congestion rate, SU dropping rate, PU congestion rate, and other performance indicators. Network Selection of Multiple primary Networks is a key technology in dynamic spectrum access.

Network Selection

Network selection is divided into offline network selection and online network selection.

Offline Network Selection

The problem of off-line network selection is that in the current network state, each SU has equal probability of accessing PRNs. Therefore, the performance of CRN system varies greatly with network selection. The network selection problem in multiauthorized cognitive radio networks can be described as shown in Fig. 3.

Offline network selection scheme mainly includes random network selection scheme, greedy network selection scheme based on number of idle channels, and weighted network selection scheme.

Random network selection scheme refers to the random and equal probability selection of an authorized network access from multiple primary networks. Random network selection scheme is the simplest, and almost no SU control. However, due to randomness, the differences among PRNs are not taken into account, such as the number

Dynamic Spectrum Access in Multiple Primary Networks, Fig. 2
work flow chart of CRNMPNS

Dynamic Spectrum Access in Multiple Primary Networks, Fig. 3
Network selection description diagram

of shared channels, the constraints of PRNs on CRNs.

The greedy network selection scheme based on the number of idle channels is that the SU to be accessed chooses the authorized network access

scheme with the largest number of idle channels at the current time. Greedy network selection scheme always chooses the best PRN access in the current network, which can achieve load balancing effect to a certain extent and reduce SU

dropping rate. Under unconstrained conditions, it should be the optimal network selection scheme.

The weighted network selection scheme is based on the weighted PRNs. For the PRNs with more shared channels, the weighted PRNs are larger, and access is based on the proportion of the weighted PRNs. Weighted network selection scheme can effectively improve spectrum utilization, reduce SU dropping rate, and improve SU quality of service.

Online Network Selection

Because of the dynamic changes of network environment, when some factors change, the off-line network selection scheme will not meet the needs of dynamic environment. Therefore, online network selection is proposed, that is, network selection scheme and simulation environment will be dynamically adjusted with the change of parameters.

Because the problem of off-line network selection is based on the prior conditions of PU and SU, the corresponding expression of measurement index is obtained by theoretical deduction. Once the network environment changes, it needs to be recalculated and deduced to obtain closed solution, so the network cannot be dynamically adjusted. Moreover, the priori conditions of PU and SU such as arrival rate and service time are unknown in real environment. Online network selection do not need the priori conditions of PU and SU that makes this network selection scheme fits better in dynamic environment.

Online network selection scheme mainly includes ONUP network selection scheme, ONUP & Greedy network selection, and ONUP & Min network selection.

ONUP network selection scheme is to update the network selection scheme online. The basic idea of this scheme is to update the collision probability of PU as long as the corresponding network state changes. Because the impact factors of the collision probability of PU include the number of PU access channels and the number of PU preempted channels from SU, when PU access

the idle channel or PU preempt SU channels, the collision probability will be recalculated.

ONUP & Greedy network selection scheme adds a judgment process on the basis of ONUP network selection. When the collision probability is larger than the upper limit, judgment is added to find out the largest number of idle channels in the current state within a certain range of guaranteeing the maximum collision probability. If the number is greater than 2, the priority is 1 in the current state, and if it is not satisfied, the priority is infinitesimal. When the number of idle channels is more than 2, it is guaranteed that the transmission will not be interrupted because of the random arrival of PU when the idle channel is accessed.

ONUP & Min network selection scheme chooses the access with the lowest collision probability when the collision probability is greater than the collision probability.

Summary

In this chapter, we introduced the application background of multiple primary networks. The topological structure of multiple primary networks is based on heterogeneous networks. Unlike other networks, dynamic spectrum access of multiple primary networks has network selection process. Two kinds of network selection scheme offline and online selection are introduced. Online selection fits better in dynamic wireless communication environment than offline selection.

Synonyms

Cognitive radio; Dynamic spectrum management

Definitions

Dynamic spectrum access is a radio technology that can dynamically select a licensed spectrum within a proper access right to communicate in a time, space, and frequency domain. This is a communication mechanism that allows unauthorized user (also known as Secondary user, SU) to access the licensed spectrum for communication without interfering with the authorized user (Primary user, PU) communication.

Historical Background

Due to the limited spectrum and strict government control, the spectrum resources are scarce and expensive. Dynamic spectrum access is a powerful technology to support the development of wireless communications and network. The concept of dynamic spectrum access was first proposed by the NeXt Generation Program, which was established in 2003 by Defense Advanced Research Projects Agency (Akyildiz Ian et al. 2006).

Later on, the IEEE Standard Association (IEEE SA), IEEE Communications Society (ComSoc), and IEEE Electromagnetic Compatibility (EMC) jointly established the IEEE P1900 Standardization Committee and formally defined the concept of dynamic spectrum access in 2005. The IEEE P1900 goal is to support the standardization of next-generation

radio and advanced spectrum management technologies. In 2007, the IEEE Standards Board approved IEEE P1900 reorganization as Standards Coordinating Committee 41 (SCC41), Dynamic Spectrum Access Networks (DySPAN). Then, SCC41 was directly under the IEEE ComSoc Standards Board and renamed the IEEE Dynamic Spectrum Access Networks Standards Committee (DySPAN-SC) in 2010. IEEE DySPAN-SC redefines the scope of SCC41 research (Prasad et al. 2008), including dynamic spectrum access radio systems and networks with the focus on improved spectral efficiency; new technology of dynamic spectrum access based on spectrum interference management; network management and information sharing between multiple network technologies.

In 2010, Federal Communications Commission (FCC) issued a policy to open digital TV white space (TVWS) to unauthorized commercial device, allowing unlicensed users to use TVWS with authorized users, without disrupting digital TV broadcasts and wireless microphone users (FCC 2010). On June 13, 2012, the FCC released Notice of Proposed Rulemaking (NPRM) on the 4.9GHz public safety radio. Based on the work of the FCC, IEEE 802.11 has established the IEEE 802.11af working group to standardize WLAN services for the TVWS band.

In addition, the “Dynamic Radio for IP Services in Vehicular Environments, DRiVE” project by the European Telecommunications Standards Institute (ETSI) aims to use the public coordination channel to achieve dynamic sharing of spectrum resources between heterogeneous networks (Khattab et al. 2013). As a preliminary research on the key technologies of dynamic spectrum sharing, this project provides a sufficient technical reserve for dynamic spectrum access. “Specific Efficient Uni- and Multicast Over Dynamic Radio Networks for IP services in Vehicular Environments, OverDRiVE” project in ETSI aims to enhance and coordinate the Universal Mobile Telecommunication System (UMTS) wireless network to ensure efficient use of spectrum in vehicle multimedia services. As an extension of the DRiVE/OverDRiVE project, ETSI launched the “End to End

Reconfigurability, E2R” research project, which aims to use software defined radio to fuse different types of wireless networks in the future, enabling end-to-end reconfigurability and coexistence of multiple wireless access systems such as cellular, wireless LAN, and digital video broadcasting.

Foundations

Cognitive Radio

Based on software radio technology, Joseph Mitola 2000 was the first to give the following definition of cognitive radio in his PhD thesis (Mitola 2000). In his paper, he explained how cognitive radio could improve wireless services through Radio Knowledge Representation Language (RKRL). Cognitive radio should make full use of the intelligent computing capabilities of wireless digital devices and related networks in radio resources and communications to detect user communication demands and provide the most appropriate radio resources and wireless services based on these needs. As shown in Fig. 1, in a cognitive radio system, the system constantly observes changes in the environment and state and continuously learns to formulate corresponding optimal strategies to process the events. Therefore, in order to achieve dynamic

spectrum access, the most basic condition is that the SU is equipped with cognitive radio. Those SU form a cognitive radio network (CRN). In this context, these three paradigms are known as interweave CRN, underlay CRN, and overlay CRN (Goldsmith et al. 2009).

Interweave CRN

Interweave CRN differs from the others CRN in that PUs has absolute priority in using spectrum, which means that when the PU is using this licensed spectrum, SUs cannot access the band. Therefore, the Interweave CRN is also known as opportunistic spectrum access, in which case the SU can exploit spectrum gaps in time, space, or frequency domain. As shown in Fig. 2, SUs use cognitive radio technology to perceive the surrounding spectral environment and then select one or more idle spectrum. The SUs transmitters convert them into a selected spectrum for transmission. Due to opportunistic spectrum access, SUs are highly unstable in communication, and SUs transmission performance degrades when PU reclaim the spectrum.

Underlay CRN

The underlay CRN allows SUs to access licensed spectrum regardless of whether the PUs are accessing, and the PUs can tolerate interference from all SUs, which means some threshold

Dynamic Spectrum Access Through Cognitive Radio Networking, Fig. 1 Cognition cycle

Dynamic Spectrum Access Through Cognitive Radio Networking, Fig. 2
Interweave CRN spectrum

Dynamic Spectrum Access Through Cognitive Radio Networking, Fig. 3
Underlay CRN spectrum by using UWB

constraints are required in PUs receivers. There are two methods to satisfy this constraint. In the first method, ultra-wide band (UWB) technology that allows signals to have a bandwidth of GHz by directly modulating the impulse pulses with very steep rise and fall times is used to enable SUs transmit information to propagate over a wide spectrum. As shown in Fig. 3, it causes the interference of the SUs on the licensed spectrum far below the threshold in the PU receiver. This method is mainly used for short-range communication due to the low transmission power of SUs. The second method is called the interference temperature – interference temperature that a model quantifies and manages interference recommended by the FCC at the end of 2003. In the interference temperature mechanism, the interference temperature is used to characterize the sum of the interference generated by the SUs and the system noise power at the PUs receivers. The SUs can use the licensed spectrum if the interference at the PU receiver does not exceed the interference temperature threshold. In this way, SU can transmit data at a higher power on the licensed spectrum.

Overlay CRN

Compared with the underlay CRN, the overlay CRN also allows SUs to coexist with the PUs. However, the difference between overlay CRN and underlay CRN is that SUs can use the information of the PUs to select and optimize the corresponding communication methods. In the underlay CRN and interweave CRN, the PUs do not need to know whether the SUs exist or not, and there is no interaction between them. In the overlay CRN, PUs can gain benefits by establishing a cooperative relationship with the SUs, and the SUs can use the PUs spectrum for transmission. The cost of the SUs using the licensed spectrum to obtain transmission opportunities is to provide services to the PUs so that the PUs can transmit its information to its intended destination with greater reliability. In this way, PUs and SUs mutually benefit from cooperation, i.e., the PUs and the SUs cooperate to achieve mutual benefit. The negotiation of SUs and PUs is required to implement the overlay CRN. As shown in the Fig. 4, the PUs enable SUs to use the spectrum by completely or sharing a spectrum. When the SU and the PU share a part

**Dynamic Spectrum
Access Through

D

of the spectrum, channel coding or network coding is adopted to eliminate interference between them.

Spectrum Sensing

Different from the traditional wireless communication system, the goal of dynamic spectrum access of CRN is to improve the utilization of spectrum resources and satisfy the communication of SUs under the premise of satisfying the interference requirements of the PUs. In order to meet the requirements in the CRN, the SUs must have more accurate spectrum sensing capability than traditional wireless communication users. Spectrum sensing can generally be divided into local spectrum sensing and cooperative spectrum sensing (Ramani and Sharma 2017). The most effective method to improve accurate spectrum sensing at present is cooperative spectrum sensing. Under local spectrum sensing condition (such as energy detection, matched filter, cyclostationary detection, and wavelet detection), the effects of the SNR will deteriorate and limit the sensing in a low signal-to-noise ratio (SNR) environment. In addition, a hidden terminal problem may be caused, that is, SUs are shadowed in severe multipath fading environments or inside buildings with high penetration loss. In these cases, the SUs may not be able to detect the presence of the PUs and will then access the licensed spectrum and cause severe co-channel interference to the PUs. Cooperative spectrum sensing can obtain better sensing accuracy than local spectrum sensing, reduce local spectrum

sensing complexity and detection time, and solve Hidden Stations problem.

According to the difference of the location of the spectrum sensing decision, it is divided into distributed and centralized cooperative spectrum sensing. SUs in different locations simultaneously perform local spectrum sensing and upload the sensing result or sensing data to the fusion center of the upper level. The fusion center then determines the existence of the PUs through some data fusion algorithm, such as hard decision fusion, soft decision fusion, and quantized decision fusion. In distributed cooperative sensing, neighboring users exchange their respective local spectrum sensing results and then make their own judgments and decisions. This approach does not require a central control node and reduces signaling interactions.

Cooperative CRN

Although cooperative spectrum sensing between SUs has satisfactory performance, they have a highly complex implementation. In addition, even if the SUs have accurate sensing capability, the spectrum sensing-based method cannot fully guarantee the transmission performance of the SUs in interweave CRN. Because the SUs must abandon its transmission when they detect the presence of the PU, and sense another spectral hole for transmission. If no spectrum is available, the SUs must stop transmitting. The main reason for this problem is due to the lack of cooperation between PUs and SUs.

SUs can achieve a reasonable cooperative relationship with PUs by providing benefits to PUs,

and SUs obtain the right to authorized spectrum access from PUs. This is called cooperative CRN (CCRN) (Cao et al. 2016). There are two promising approaches in CCRN, cooperative communications and spectrum leasing between PUs and SUs. For cooperative communication in CCRN, the cost of the SUs is that the SUs improve the communication quality of PUs, which one or more SUs can act as relaying nodes for a PU. In this case, the PUs communication links can be established with the help of SUs multihop transmission, which can obtain diversity gain and enhance reception by appropriately combining signals from the multipaths for PUs. As a result, spectral efficiency and utilization are significantly improved. Due to the different channel conditions between the SUs and the PUs, the PU needs to select the SUs that provide the appropriate relay service. The SU uses the additional transmit power to forward the PU information, so that the SU needs to evaluate its gain and cost and select the most suitable PU as its partner.

Since the PUs can transmit by purchasing an authorized spectrum, the SU can lease the spectrum from the PU to achieve the communication requirements. Similarly, the incentive for PU in CCRN comes from the rental spectrum to obtain revenue. In a spectrum-leasing model, the biggest challenge is the pricing issue, which is due to the competition between the PUs selling spectrum and the auction spectrum between SUs. This situation often leads to very complicated pricing strategies. In order to solve the pricing problem, some economic models be used in spectrum leasing to meet PU revenue and SU communication quality. Since the propagation of radio in space is attenuated, the spectrum can be multiplexed in different regions, which means that SUs in different regions can share the spectrum. Since the spectrum usage of the PU is dynamic, offline auctions such as VCG cannot be used. An online auction mechanism based on the above characteristics is used to efficiently allocate spectrum resources (Sodagari et al. 2011). This online auction mechanism has multiple winners and the ability to complete auctions quickly. More information about spectrum

auctions can be found in the literature (Pastircak et al. 2014).

Key Applications

Dynamic spectrum access improves the efficiency of spectrum resources.

Future Directions

According to the current trend, it is a research direction for dynamic spectrum access to achieve smarter by deep learning. In addition, security issues, more accurate spectrum sensing, and applications towards 5G are also research hotspots for dynamic spectrum access.

Definitions

Edge computing is a method of optimizing cloud computing systems by taking the control of computing applications, data, and services away from central nodes to the edge of the network. *Video analytics* is the capability of automatically analyzing video contents to detect and determine temporal or spatial events.

Historical Background

Satyanarayanan et al. (2009) first discussed the technical obstacles of mobile computing

and proposed a new architecture named as *cloudlet*, which is then unified into *edge cloud*. With an edge cloud, a mobile user exploits virtual machine (VM) or container technology to rapidly instantiate customized service and then uses that service over a wireless network. Generally, the edge cloud can be regarded as a trusted, resource-rich computer or cluster that's well-connected to the Internet and available for use by nearby mobile devices. Following the concept of edge computing, many works conducted case studies and presented challenges in the field of edge computing, especially for computation-intensive applications. For example, Ahmed and Ahmed (2016) discussed promising mobile edge computing scenarios, where video stream analytics is one killer application. Shi et al. (2016) highlighted some challenges and opportunities on edge computing in programmability, naming, data abstraction, service management, security and privacy, as well as optimization metrics that are worth future research and study.

A key benefit of utilizing edge computing is the capability to achieve high-throughput access, real-time processing guarantee, and energy saving. In the following, we will review some existing researches on video analytics system with edge computing from three aspects, processing efficiency, energy saving, and video characteristic extracting.

The concept of edge computing helps enhance communication bandwidth and reduce task processing time on real-time video stream analytics system design. Satyanarayanan et al. (2015) proposed a federated system of VM-based cloudlets that perform video analytics at the edge of the Internet, thus reducing the demand for ingress bandwidth into the cloud. To improve the efficiency of edge clouds, Salsano et al. (2017) introduced the architecture with dynamic deployment and composition of virtual functions and implemented a video streaming service exploiting mobile edge computing functionalities. To provide better scalability to the cloud-based solutions, Drolia et al. (2017) employed selective computation on the devices to reduce the need to off-load images to the cloud. In coordination

with edge servers, it uses prediction to prefetch parts of the trained classifiers used for recognition onto the devices and uses these smaller models to accelerate recognition on devices. Furthermore, Ren et al. (2018) proposed an edge computing-based object detection architecture to achieve distributed and efficient object detection via wireless communications for real-time surveillance applications. Overall, the benefits of real-time processing brought from edge computing lie in the high-throughput guarantee with edge clouds deployed in proximity.

In most of current mobile systems, many operations are conducted on the handheld devices, e.g., smartphones. As a result, developers worldwide are building increasingly complex applications that require ever-increasing amounts of computation resources and energy. Thus, the energy issue cannot be ignored, and fortunately this problem can be solved with the conception of edge computing. Cuervo et al. (2010) presented MAUI, a system that enables fine-grained energy-aware offload of mobile code to cloud. Kosta et al. (2012) proposed ThinkAir, a framework that makes it simple for developers to migrate their smartphone applications to cloud, which provides method-level computation offloading. Off-loading computation-intensive tasks to edge clouds can enhance energy efficiency, if the energy saving in computation processing is greater than the increased wireless transmission energy consumption.

To propose an efficient edge computing system for real-time video stream analytics, characteristics of video contents should also be taken into consideration. Bilal and Erbad (2017) highlighted some of the potentials and prospects of edge computing for interactive media and presented some preliminary works on how edge computing can be used to tackle various challenges. Ran et al. (2018) designed a framework that ties together front-end devices with more powerful back-end "helpers" to allow deep learning to be executed locally or remotely in the cloud/edge. They considered the complex interaction between model accuracy, video quality, battery constraints, network data usage, and network conditions to determine

an optimal offloading strategy. Wang et al. (2018) proposed an adaptive wireless video transcoding framework based on the emerging edge computing paradigm by deploying edge transcoding servers close to base stations. It is essential to efficiently extract video characteristics and then apply them into edge computing architecture design.

In summary, utilization of edge computing in video analytics can help save cost, bandwidth, energy, etc. Some special characteristics from video content or edge servers can be further exploited to enhance the system efficiency.

Foundations

In the environment of edge computing for video stream analytics, computation tasks can be off-loaded to edge servers to reduce latency and increase throughput. A task can be off-loaded to a nearby edge server, which returns the results back when the computation task is completed. To design a real-time video stream analytics in the edge computing architecture, we will face some new challenges:

- *Air interface management.* The wireless transmission will be severely affected by the interference among users. For example, the uplink data rate of a mobile user that chooses to off-load the computation to the edge server via a wireless channel can be modeled as

$$R = B \log \left(1 + \frac{P}{N_0 + I} \right) \quad (1)$$

where B is the channel bandwidth, P is the user transmission power, N_0 is the noise power, and I denotes the summarized interference power. It is important to schedule appropriate number of tasks to be served by edge server.

- *Frame extraction pattern.* As stated by many works, e.g., Lu et al. (2018), performing object detection in a video entails two main steps.

First, video frames must be extracted from the video and turned into images. To target objects with different dynamics within the video, the task issuer may request different frame extraction rates. For example, for an object moving at a high speed like a car, the rate should be high enough to not miss the object. For a slowly moving object like a pedestrian, a lower frame extraction rate can be used, which eases the computing burden. The setting of the frame extraction rate for object detection is important, which should be considered in the video analytics structure design.

- *Real-time scheduling design.* After the frames are extracted from the original video, object detection is performed on the images. The detection function may be performed locally on mobile devices, on edge servers, or on remote clouds or distributed among them. It is the task issuer's query requirements and the resource usages of mobile devices that should be considered in scheduling design.
- *Distributed edge colony.* The edge servers can be combined with each other to form a colony that can provide more powerful computing resources. In the realistic scenario, some mobile stations, e.g., the vehicles or even the mobile phones, can be regarded as the member of edge colony. The mobility of the edge server will introduce new problems, including "the dynamic edge computation capacity," "the information exchange between mobile nodes," etc.
- *Data consistency and integrity.* The captured video contents can be stored in the edge servers or remote cloud. Esposito et al. (2017) stated that it is important to cope with scalability, persistency, and reliability requirements and to adapt the infrastructure capacity to the exacting needs based on the amount of generated data. It is important to guarantee the data consistency and integrity in video analytics database design.

These challenges should be focused in applying edge computing technology into video analytics system design.

Applications

In education assistance applications, we design an edge computing framework for real-time video stream analytics, where the architecture can be found in Fig. 1. There are three key layers in our proposed edge computing architecture for real-time video stream analytics, including:

- **The user application layer.** In this layer, the camera will record the video shots for all the students' actions in the observed vision. After cumulating for a given period, the camera will off-load the captured video stream to the nearby edge server. The teacher with a handheld device can directly access the real-time processed student state information retrieved from the edge server.
- **The edge service layer.** In this layer, the edge server will conduct the video stream analytics

timely and send the required data back to the user (i.e., teacher). To enhance the tractability and efficiency of the edge computing architecture, the edge servers are combined into a colony. A leader edge node is elected to guarantee the load balance between different servers.

- **The cloud and database layer.** In this layer, an offline checking system is installed into the remote cloud server. After class, if the teacher has the interests to review the students' state of learning, he can check from the remote cloud. The video contents, in a specific period, can be stored in database for offline check.

The three layers should be jointly designed to construct a complete and efficient video analytics system with edge computing.

Edge Computing for Real-Time Video Stream Analytics, Fig. 1 An edge computing architecture for real-time video analytics in education assistance system

Future Directions

Edge computing paves a new way on video stream analytics, and the following up work possibly includes:

- *Multiview video stream analytics.* As shown in the classroom 1 of Fig. 1, the students' activities can be observed in different points of view. The video stream analytics results are overlapped with each other, which motivates a more efficient edge service schedule among them.
- *Multimodal information fusion.* Many multimodal information can be captured from the video stream, e.g., the face recognition information from the image and the voice information from the audio data. These information can be integrally learned to enhance the system performance. For instance, if the voice information from the acoustics is not detected, it might imply that the teacher is not teaching. In this case, the video analytics tasks might not be that urgent, which can be off-loaded to remote cloud.
- *Interactive video system.* In our previously discussed system, the video contents can only be uploaded to the edge servers, while user can receive this information afterward. In realistic word, a more interactive system is preferred, e.g., when the students who are observed can also receive analytics alerts, a more refined teaching ecosystem can be obtained.

Researches on these directions will further enhance system performance, which can be regarded as an efficient supplement to current video analytics architecture.

Definitions

Edge data centers (EDCs) in fog computing bring some functionalities and capacities from centralized data centers to the network edge in order to meet the requirements of near-the-edge data service subscribers.

Historical Background

Centralized DCs (CDCs) are hard to handle the latency-sensitive data streams and the burst since they are usually deployed far away from subscribers. Fog computing brings the capacity from centralized data centers to the edges, providing low-latency, context-aware, high-availability, and distributed data services. EDCs are also responsible for data compression, de-duplication, and desensitization to ensure efficiency and safety. Some researches focus on the architecture of EDCs in fog computing environment. Zhang et al. in Zhang (2016) proposed a three-layer architecture consists of end users, operators, and fog nodes and provided distributed decisions to make full use

of computing resources by Stackelberg games. The work in Puthal (2018) studies the load balancing in EDCs in the aim of providing secure and sustainable services, balancing workloads between fog nodes, and backing up to make EDCs fault tolerance. Furthermore, Tan (2017) gave a load prediction approach to improve the rate of resource utilization in EDCs. Some other researches focus on the proper integration of CDCs and EDCs and to extend their advantages to extremity. Wang et al. in Wang (2018) focused on requirements of the Internet of things (IoT) and came up with a three-layer architecture where EDCs lie at the middle. The latencies of services of this architecture are evaluated, compared with CDCs-only scenarios. Sajjad (2016) proposed an approach for the deployment of geographically distributed data applications in order to reduce latencies and bandwidth utilities. There are also researchers studied EDCs in a software-defined networking (SDN)-based perspective, for example, in Martinello (2017), the authors proposed a programmable architecture of EDCs in term with key technologies applied in the architecture. The main idea is to decouple functions between edge and center, making the whole architecture flexible and intelligent. Dominicini et al. provided their researches over the network functions virtualization (NFV) in EDCs, bringing efficient orchestrations for service-centric architectures in Dominicini (2017). In addition, applications based on EDCs are considered in several other literatures. Sharma (2017) and Teranishi (2017) studied to apply EDCs in Internet of things networks or in dynamic data processing applications.

Foundations

The architecture of the data centers combined with fog computing can be divided into three layers. Apart from access networks layer and centralized data centers layer, edge data centers, deployed with some computing and storage devices, serve as the middle layer. The key idea is to treat the CDCs as a pool with massive computing and storage resources while process-

ing the real-time data streams over the edges. This kind of coordination can bring huge advantages for data services. The EDCs are formed up with several fog nodes in an orchestrated and distributed manner. One challenge related to EDCs is that both the capacity and the coverage are limited in fogs, for the reason that efficient resource management is critical to high QoS. Several ways can help manage resources in EDCs, for instance, giving the ability of adaption and adjustment of capacity of EDCs. The EDCs may also face the drastic fluctuations of data loads brought by the movements of users and the types of applications. With the help of location information in fog computing and proper learning algorithms, the EDCs can adjust promptly along with the movements of subscribers. Load balancing can also be deployed in fog computing to reassign data streams to different EDCs in order to equilibrate loads among them and stabilize the response time for subscribers. Another advantage which can be brought by load balancing is the high availability of EDCs services since load balancing can ensure the consistency of services by redirect loads of failed fog nodes to the surviving ones in the fog computing clusters. The nature of geographical distribution enables high availability for EDCs since they can backup each other over malfunctions. Both CDCs and EDCs have their own benefits. In the perspective of CDCs, EDCs play as an integral part which is supposed to provide data streams that are processed. In addition, EDCs should provide a set of APIs for CDCs to hide the heterogeneity. The harmonized cooperation between CDCs and EDCs offers end users with huge capabilities and low latencies of data services. One efficient way of integration is introducing the paradigms of SDN and NFV. With the decoupling of control plane and data plane, EDCs can provide flexibility for the deployment of network functions in fog computing. As a consequence, intelligence can be brought to improve the expandability and robustness. On the other hand, SDN architecture distinct nothing between CDCs and EDCs, they can function in a conjunct way. Thus, data services can be deployed and managed in an easy way.

Key Applications

Edge data centers are used in every environment where low-latency services are required to be moved from data centers to the fog, for example, content delivery, Internet of things, and intelligent transportation systems.

Future Directions

Unlike CDCs, EDCs are under the intimidation of viciousness. Security is vital in the fog environments. Therefore, EDCs needs to be deployed with critical arrangement of security. On the other hand, the drastic changes of physical channels bring another challenge to the application of data centers in fog computing.

Licensed-assisted access (LAA); LTE-unlicensed (LTE-U); Quality-of-service (QoS)

Definition

Licensed-assisted access (LAA) or LTE-unlicensed (LTE-U), is a promising technology to offload dramatically increasing cellular traffic to unlicensed bands, exploiting Listen-before-talk (LBT). The main goal is to achieve effective utilization of unlicensed spectrum and fair coexistence with legacy systems such as IEEE 802.11 WiFi.

Historical Background

In the recent years, the increasing prevalence of smart hand-set device (e.g., mobiles, laptops) has triggered an explosive growth of mobile data stemming. Forecasts from Cisco show the traffic demand is expected 1000 times as much traffic by 2020 (Cisco Visual Networking Index 2015). The scarcity of spectrum is becoming the bottleneck to further boost the capacity of wireless communications (Zhang et al. 2015a). To fundamentally break through this predicament, academia and industry paid attention to more available spectrum opportunities, such as industry, science, and medicine (ISM) bands in 2.4 GHz, the unlicensed national information infrastructure (U-NII) bands in 5.8 GHz, etc. An emerging technology to supplementary utilization of the unlicensed spectrum, called licensed-assisted access (LAA) or LTE-unlicensed (LTE-U), has been launched into the standardization by Third Generation Partnership Project (3GPP) (3GPP 2015). The protocol also remains the strongest candidates for the upcoming 5G cellular communication standard on the exploitation of the unlicensed spectrum (RP-170828). Originally designed to off-load excessive traffic for the downlinks from the licensed bands, the protocols have also been considered for the uplink applications in the unlicensed band (3GPP 2015). Different from Wi-Fi APs, the underlying network infrastructure can coordinate between LAA stations in the unlicensed bands and base stations in licensed bands. Signaling, such as channel state information (CSI) and channel quality indicator (CQI), can also be instantly fed back from user terminals to LAA stations, through the licensed band, thereby facilitating fast power control and user scheduling of LAA in the unlicensed bands.

The LAA technology is still in its infancy, and there are a few critical challenges arising in network coexistence among different radio access technologies, spectrum sharing, and access (Yu et al. 2016). The major challenge is how to guarantee the fair and effective coexistence between LAA-enabled small base stations

(SBSs) and Wi-Fi. Then, future 5G systems will support a variety of applications with wide-ranging QoS requirements, including VoIP, virtual reality, multimedia streaming, machine-type communications, as well as traditional web browsing and file transfer. The random arrived traffic and the random access mechanism of LAA become an obstacle to guarantee QoS. Furthermore, the new LAA procedures may have impacts on energy consumption of mobile devices due to the extra energy used for channel detection and packet collision. Lastly, due to the time-variant wireless channel conditions and the dynamic variation of the number of Wi-Fi nodes (e.g., Wi-Fi stations, Wi-Fi APs) in the overlapping areas, LAA-enabled SBSs need a dynamic spectrum access mechanism to switch to an unlicensed channel with very-low-level interference and leverage the traffic between the licensed and unlicensed bands.

As for the coexistence of SBSs and Wi-Fi, two kinds of specifications are proposed: frame-based mechanism (FBM) where SBS is activated at periodic cycles on unlicensed band and load-based mechanism (LBM) where SBS competes for the unlicensed channel using listen-before-talk (LBT) and backoff procedure like Wi-Fi (3GPP 2015; [Broadband Radio Access Networks \(BRAN\)](#)). Zhang et al. (2015b), Al-Dulaimi et al. (2015), and Ratasuk et al. (2014) design coexistence mechanisms, such as an almost blank sub-frame (ABS) scheme, an interference avoidance scheme (Zhang et al. 2015b), and adaptive listen-before-talk (LBT) mechanism (Zhang et al. 2015b; Ratasuk et al. 2014). To improve the system throughput, Rupasinghe and Güvenç (2015) propose a Q-Learning based dynamic duty cycle selection technique for configuring LTE transmission gaps. Almeida et al. (2013) propose a coexistence scheme by allocating the almost blank sub-frames to improve the Wi-Fi throughput per user up to 50 times. In Han et al. (2016), an LBT-based MAC protocol is developed, where the transmission durations of LAA devices are optimized to maximize the system throughput. In Voicu et al. (2016), a comparison study is conducted between the approaches using duty cycle and LBT and revealed the effectiveness of

LBT in the case of strong interference. The above works mainly focus on the design of coexistence mechanisms or improving the system throughput, without considering the QoS issue and the dynamic varying of wireless environment.

A few number of works have studied on QoS or energy efficiency (EE) requirements of SBS in the unlicensed band. Yin et al. (2016) develop a power allocation algorithm to obtain pareto-optimal between minimization of interference in the licensed band and collision in the unlicensed band by the weighted Tchebycheff method while satisfying the rate requirements of users. Chen et al. (2016) first investigate joint licensed and unlicensed resource allocations to maximize the EE through Nash bargaining when LAA systems adopt a FBM method.

Foundations

As specified in 3GPP TR 36.889 (3GPP 2015), two different channel access schemes are considered for LAA, i.e., LBT with random backoff in a fixed CW and LBT with random backoff in an exponentially increasing CW, as illustrated in Fig. 1a, b, respectively. These two methods are referred to as FCW (Fixed CW) and VCW (Variable CW), respectively.

In the case of FCW, a LAA-BS senses the unlicensed band for a predefined period, termed “channel clear assess (CCA),” whenever it has packets to transmit. If the channel is free over CCA, the LAA-BS sets an integer backoff timer randomly and uniformly within a fixed CW $[0, W_L]$, where W_L is the initial CW size. The backoff timer counts down one per timeslot. It freezes if the channel is busy and does not resume until the channel is sensed free for CCA again. Once the backoff timer turns to zero, a (re)transmission is triggered. If the (re)transmission is collided (i.e., no acknowledgment (ACK) is returned), the LAA-BS resets the backoff timer within $[0, W_L]$ to retransmit the packet.

In the case of VCW, exponential backoff is adopted on top of FCW, where the CW doubles, each time the (re)transmission of the LAA-BS

Effective Utilization of Unlicensed Spectrum, Fig. 1 Medium access mechanism for unlicensed spectrum: (a) LAA FCW and (b) LAA VCW, where the initial CW

of LAA is 8, and η_j is the number of backoff timeslots in response to the j -th collided (re)transmission, $j = 0, \dots, K_L - 1$

is collided (i.e., no ACK is returned). K_L is the maximum number of retransmissions per packet, after which the CW is reset to W_L . In this sense, VCW is analogous to the distributed coordination function (DCF) of Wi-Fi (Bianchi 2000). However, the LAA-BS resets the CW to W_L , after a collision-free (re)transmission (i.e., neither ACK nor non-ACK is returned), as opposed to the DCF. This is due to the fact that the LAA-BS can exploit OFDMA to multiplex signals for multiple LAA-UEs. It is possible that only some of the LAA-UEs succeed and return ACKs after a collision-free (re)transmission (3GPP 2015). Resetting the CW can prevent the CW from continuously enlarging and staying large.

Unfortunately, it is difficult to preserve reliability in the unlicensed spectrum which is primarily dominated by uncoordinated transmissions of contention-based wireless devices. Erratic collisions between the uncoordinated transmissions can breach the delay requirements of traffic and even cause significant packet losses. The ultra-dense deployment of networks could further deteriorate the reliability in the unlicensed spectrum. Moreover, there is typically no policy to regulate the deployment of wireless transmitters in the unlicensed band, given the distributed nature of the networks and devices. The literatures Cui et al. (2017, 2018) have propose a novel effective capacity to quantify the maximum consistent data rate of a link without violating the QoS in

unlicensed spectrum. Potential practical applications of the new measure are also discussed.

QoS-aware Power Control

The maximization of the effective capacity in unlicensed spectrum can be formulated by optimizing the power of a transmitter concurrently sending data to multiple receivers using orthogonal frequency-division multiple access (OFDMA) techniques. By exploiting the concavity of the effective capacity, the problem can be reformulated to be a convex optimization problem which can be straightforwardly solved by using standard convex techniques, such as interior-point method and sub-gradient method.

QoS-aware Bandwidth Allocation

The effective capacity can also be used to facilitate the bandwidth allocation in the case that a LAA transmitter serves multiple receivers with nontrivial QoS requirements. Exploiting the concavity of the effective capacity with respect to the instantaneous transmit rate, the bandwidth allocation can be formulated as a convex optimization problem which is readily solved by using standard convex techniques.

Other Applications

Another application example of the effective capacity is to maximize the effective energy efficiency of transmitters in unlicensed spectrum.

This is an extension of the above effective capacity maximization, since the effective energy efficiency of a transmitter is defined to be the ratio of its effective capacity to its transmit power. By exploiting the aforementioned concavity of the effective capacity again, as well as fractional programming techniques, the maximization of the effective energy efficiency can be formulated to be a parametric convex problem and recursively solved by using the KKT conditions and the Dinkelbach's method.

Definitions

An economic system is efficient if the resource production and allocation maximizes the total payoff of all agents in the system. More generally, a system is efficient if the system state maximizes a desired performance metric (such as the total utility of all entities in the system) given the inputs to the system.

An economic system is Pareto-optimal if there does not exist alternative resource production and allocation that improves at least one agent's payoff without reducing any agent's payoff. More generally, a system is Pareto-optimal if there does not exist an alternative system state that makes at least one preference metric (such as some entity's utility) better off without making any preference metric worse off.

Historical Background

The concept of Pareto efficiency is named after Vilfredo Pareto who was an Italian engineer and economist. He used the concept in his studies of economic efficiency and income distribution. Pareto efficiency is closely related to two fundamental theorems. The first fundamental theorem was first demonstrated graphically by economist Abba Lerner and first mathematically by economists Kenneth Arrow and Gérard Debreu. It states that given certain assumptions, competitive markets produce Pareto efficient outcomes (Hindriks and Myles 2013). This captures Adam Smith's "invisible hand" hypothesis, namely, that competitive markets tend toward an efficient allocation of resources (Mas-Colell et al. 1995). The second fundamental theorem states that given further restrictions, any Pareto efficient outcome can be supported as a competitive market equilibrium (Hindriks and Myles 2013).

Key Points

The efficiency of a system is usually measured in terms of the social welfare, which is the total utility of all entities in the system. It is often

a desirable objective for system designers and has been used in many applications including economics and engineering. The metric of efficiency is in stark contrast to fairness, which is often concerned with maximizing the minimum utility among all entities in the system. As a result of this difference, an efficient system can be quite different from a fair system and may not be fair.

Pareto optimality is a weaker notion than efficiency, in the sense that an efficient system (measured by social welfare) must be Pareto-optimal, but the converse may not hold. Pareto optimality is considered a minimal notion of "efficiency" that does not necessarily result in a socially desirable state or fairness among the entities. As a result, it is almost always one of the desired objectives for system design. The concept has been applied in various fields such as economics and engineering. Simply put, a system is not Pareto-optimal if there is an alternative system state, in which further improvements can be made to at least one agent's payoff without sacrificing any other agent's payoff. If there is a state transfer that satisfies this condition, it is called a "Pareto improvement." The set of all Pareto-optimal system states constitute the Pareto frontier. A system is weakly Pareto-optimal if there does not exist an alternative system state that makes every entity better off.

The bargaining solution is an important concept that satisfies Pareto optimality. It is the solution to the bargaining problem, which is concerned with how agents share a benefit that they can jointly generate by cooperation. A prominent example of the bargaining solution is the Nash bargaining solution (Osborne and Rubinstein 1994). It is the unique solution to a two-person bargaining problem that has desired properties by satisfying the axioms of scale invariance, symmetry, independence of irrelevant alternatives, and Pareto optimality.

Applications in Wireless Networks

In the following, three example applications are presented to illustrate how efficiency and Pareto optimality are used to design, model, and analyze

wireless networks. The first two applications focus on finding the Pareto-optimal solution and its relation with the system-wide efficient (i.e., socially optimal) solution; the last application is concerned with achieving the system-wide efficient solution.

Social Group Utility Maximization-Based Pareto-Optimal Pseudonym Change for Mobile Location Privacy

To protect location privacy in a location-based services (LBS), mobile users in physical proximity can simultaneously change their pseudonyms used in the LBS (Beresford and Stajano 2003), so that their pseudonyms cannot be distinguished from each other after the pseudonym change. Since pseudonym change usually incurs considerable overhead (e.g., service interruption (Beresford and Stajano 2003; Freudiger et al. 2009)), users need adequate incentive (e.g., privacy gain) to participate. On the other hand, with the rapid growth of online social networks (e.g., Facebook, Twitter), people's behavior tend to be altruistic to their social "friends" (friends, family, colleagues, etc.), as they care about their social friends' welfare. Therefore, mobile users' socially altruistic behavior can be exploited for pseudonym change to improve their location privacy.

Based on this motivation, mobile users' socially altruistic behavior is exploited in Gong et al. (2017) to encourage them to participate in pseudonym change based on a social group utility maximization (SGUM) framework developed in Chen et al. (2016). Under the SGUM framework, each user $i \in \mathcal{N}$ makes a decision a_i on whether to participate in pseudonym change ($a_i = 1$) or not ($a_i = 0$). The privacy gain of a user participating in pseudonym change depends on how many users in its anonymity set $\mathcal{N}_{i-}$ also participate, where $\mathcal{N}_{i-}$ depends on users' physical locations. Each user i 's individual utility u_i is given by $u_i(a_i, \mathbf{a}_{-i}) \triangleq a_i \left(\sum_{j \in \mathcal{N}_{i-}} a_j - c_i \right)$ where $\mathbf{a}_{-i}$ is all users' actions except for user i . If a user participates, its individual utility is its privacy gain $\sum_{j \in \mathcal{N}_{i-}} a_j$ minus its participation cost c_i ; otherwise, it is zero. To take into account users' socially

altruistic behavior, each user i aims to maximize its *social group utility* given by $f_i(a_i, \mathbf{a}_{-i}) \triangleq u_i(a_i, \mathbf{a}_{-i}) + \sum_{j \in \mathcal{N}_{i+}} s_{ij} u_j(a_j, \mathbf{a}_{-j})$ where $s_{ij} \in (0, 1]$ denotes user i 's *social tie* with user j , which quantifies how much user i cares about user j .

Similar in spirit to the Nash equilibrium (Osborne and Rubinstein 1994) of a standard noncooperative game, the following concept applies to the SGUM game (Chen et al. 2016). A strategy profile $\mathbf{a}^{SNE} = (a_1^{SNE}, \dots, a_n^{SNE})$ is a *socially aware Nash equilibrium* (SNE) for the socially altruistic pseudonym change game (SA-PCG) if no user can improve its social group utility by unilaterally changing its strategy, i.e., $a_i^{SNE} = \arg \max_{a_i \in \{0,1\}} f_i(a_i, \mathbf{a}_{-i}), \forall i \in \mathcal{N}$.

The *social welfare* of the system is the total individual utility of all users given by $v(\mathbf{a}) \triangleq \sum_{i \in \mathcal{N}} u_i(\mathbf{a})$. A strategy profile $\mathbf{a}^{SO} = (a_1^{SO}, \dots, a_n^{SO})$ is *social optimal* if it achieves the maximum social welfare among all strategy profiles, i.e., $v(\mathbf{a}^{SO}) \geq v(\mathbf{a}), \forall \mathbf{a}$.

A strategy profile $\mathbf{a}^{PO} = (a_1^{PO}, \dots, a_n^{PO})$ is *Pareto-optimal* if there does not exist a *Pareto-superior* profile $\mathbf{a}' = (a'_1, \dots, a'_n)$ such that no user achieves a lower individual utility, while at least one user achieves a higher individual utility, i.e., $u_i(a'_i, \mathbf{a}'_{-i}) \geq u_i(a_i^{PO}, \mathbf{a}_{-i}^{PO}), \forall i \in \mathcal{N}$ with at least one strict inequality.

As a benchmark, in contrast to SA-PCG, a socially oblivious pseudonym change game (SO-PCG) is one in which all social ties $s_{ij}, \forall i \neq j$ are 0.

To quantify the system efficiency of the SNE, consider the social welfare of the best SNE $\mathbf{a}^{SNE*}$, which is the SNE of the highest social welfare among all the SNEs. Let $\mathcal{N}_{i+}$ denote the set of users whose anonymity set includes user i . It is shown in Gong et al. (2017) that the performance gap between the maximum social welfare among all SNEs and the optimal social welfare is upper bounded by $\sum_{i \in \mathcal{N}} \sum_{j \in \mathcal{N}_{i+}} (1 - s_{ij})$. This shows that the performance gap decreases as social ties increase. In particular, when users are socially oblivious (i.e., $s_{ij} = 0, \forall i \neq j$), the performance gap reaches the maximum, and the best SNE for the SA-PCG degenerates to the best SNE for the

SO-PCG; when users are fully altruistic (i.e., $s_{ij} = 1, \forall i \neq j$), the performance gap becomes 0, and the best SNE degenerates to the social optimal strategy profile.

An efficient algorithm has been developed in Gong et al. (2017) to find a Pareto-optimal SNE $\mathbf{a}^{SNE^c}$. It can be shown that the social welfare of the SNE $\mathbf{a}^{SNE^c}$ is no less than that of the best SNE for the SO-PCG.

It is shown in Gong et al. (2017) that, for the SA-PCG, when social ties increase (i.e., $s'_{ij} \geq s_{ij}, \forall i \neq j$), the set of participating users at the SNE $\mathbf{a}^{SNE^c}$ grows (i.e., $\mathcal{N}_1(\mathbf{a}^{SNE'}) \supseteq \mathcal{N}_1(\mathbf{a}^{SNE^c})$) and the social welfare of the SNE $\mathbf{a}^{SNE^c}$ increases (i.e., $v(\mathbf{a}^{SNE'}) \geq v(\mathbf{a}^{SNE^c})$), as illustrated in Fig. 1). This shows that $\mathbf{a}^{SNE^c}$ is monotonically “expanding” with respect to social ties. Intuitively, a user with larger social ties with other users is more likely to participate in favor of its social group utility, even at the cost of obtaining a negative individual utility. Therefore, when social ties become larger, more users participate at the SNE. Furthermore, as each additional participating user increases the social welfare, the social welfare of the SNE also increases.

It can be shown that the social welfare of the SNE $\mathbf{a}^{SNE^c}$ for the SA-PCG is no less than that of the best SNE for the SO-PCG. This guarantees that the social welfare of the Pareto-optimal SNE is no less than the benchmark SNE for the SO-PCG.

Efficiency and Pareto Optimality, Fig. 1 The computed SNE migrates monotonically from Nash equilibrium to social optimality

Pareto-Optimal Spectrum Access for Secondary Users in Dynamic Spectrum Sharing

Cognitive radio is expected to capture temporal and spatial “spectrum holes” in the spectrum white space and to enable spectrum sharing for secondary users (SUs). Pricing-based mechanisms have been explored as a promising approach for spectrum access, where PUs can dynamically trade unused spectrum to SUs. However, SUs may compete via random access for spectrum opportunities. In this case, it is interesting to study pricing-based spectrum access control in cognitive radio networks, where PUs sell the temporarily unused spectrum and SUs compete via random access for such spectrum opportunities.

Consider a monopoly PU market model, where the PU’s unused spectrum is fixed. Pricing-based dynamic spectrum access based on slotted Aloha has been studied in Yang et al. (2013), aiming to characterize the optimal pricing strategy to maximize the PU’s revenue. The prices for each SU to access spectrum consist of usage price p_i and flat price g_i . Given the prices, each SU will optimize its demand by maximizing its net utility. Let $U_i(s_i)$ denote the utility function and s_i be the throughput of SU i . Under random access, s_i represents the expected number of successfully transmitted packets of SU i in a period of c and can be written as $s_i = cz_i \prod_{j \neq i} (1 - z_j)$, where z_i is the spectrum access probability of SU i . Thus, the corresponding demand function of SU i can be derived as $d_i(p_i) = U_i'^{-1}(p_i)$ if $g_i \leq U_i(s_i) - p_i s_i$ and $d_i(p_i) = 0$ (i.e., SU i would not transmit when the net utility is negative), otherwise. The PU’s revenue maximization (RM) problem is to maximize $\sum_{i \in \mathcal{M}} (g_i + p_i s_i)$ subject to the constraints $s_i \leq cz_i \prod_{k \neq i} (1 - z_k), \forall i \in \mathcal{M}$, $s_i = d_i(p_i), \forall i \in \mathcal{M}$, and $U_i(s_i) - g_i - p_i s_i \geq 0, \forall i \in \mathcal{M}$.

The RM problem is nonconvex and therefore it is in general difficult to find the global optimum. Observing that the global optimum of the RM problem is Pareto-optimal, it is reasonable to consider the Pareto frontier, i.e., the set consisting of all the Pareto-optimal solutions. The

Efficiency and Pareto Optimality, Fig. 2 Sketch of the Pareto-optimal solution: the case with two SUs

solution to the RM problem has the following properties:

1. It is in the Pareto frontier.
2. It is Pareto-optimal if and only if $\sum_{i \in \mathcal{M}} z_i = 1$.

For any Pareto-optimal allocation $d_i(p_i)$, $\forall i \in \mathcal{M}$, it holds that $\sum_{i \in \mathcal{M}} z_i = 1$. Therefore, it suffices to search for the solutions in the Pareto frontier, which can maximize the RM problem. Thus motivated, it is desirable to obtain a Pareto-optimal solution to the RM problem that maximizes the sum of SUs' throughput given the SUs' budget constraints, by confining the search space to the hyperplane $\sum_{i \in \mathcal{M}} d_i(p_i) = \kappa c$, where $\kappa \in [0, 1]$ denotes the *spectrum utilization percentage* under the allocation $d_i(p_i)$, $\forall i \in \mathcal{M}$. An example with two SUs is illustrated in Fig. 2.

When SUs' utility functions are α -fair utility functions, a Pareto-optimal solution to the RM problem has been found in Yang et al. (2013). Interestingly, the Pareto-optimal solution converges to the global optimal, as α goes to zero as shown in Yang et al. (2013). When $\alpha = 0$, the PU selects the SU with the highest budget and only allows that SU to access the channel with probability 1 to maximize its revenue.

Asymptotically Socially Optimal Distributed Channel Selection in Database-Assisted Spectrum Access

The most recent FCC ruling requires that TV white-space devices must rely on a geo-location

database to determine the spectrum availability (FCC September 23, 2010). In this architecture, the database is able to tell a white-space device (secondary users (SUs) of TV spectrum) vacant TV channels at a particular location. Motivated by the successful deployments of Wi-Fi over the unlicensed ISM bands, Chen and Huang (2013) consider an infrastructure-based white-space network, where there are multiple secondary access points (APs) operating on white spaces. A key challenge for such an infrastructure-based white-space network design would be that each AP must choose a proper vacant channel to operate in order to avoid severe interference with other APs.

Consider that all the APs try to maximize the system-wide throughput (i.e., efficiency) cooperatively. Such a cooperation is feasible when all the APs are owned by the same network operator. For example, the APs that are deployed in a university campus can coordinate to maximize the entire campus network throughput. Formally, the APs need to collectively determine the optimal channel selection profile a such that the system-wide throughput is maximized (problem P1), i.e., $\max_{a \in \Theta} \sum_{n=1}^N U_n(a)$, where $U_n(a)$ is the expected throughput of AP n under the channel selection profile a . Problem P1 is a combinatorial optimization problem of finding the optimal channel selection profile over the discrete solution space Θ . In general, such a problem is very challenging to solve exactly especially when the size of network is large (i.e., the solution space Θ is large).

A cooperative channel selection algorithm has been proposed in Chen and Huang (2013) that can approach the optimal system-wide throughput and thus achieve efficiency approximatively. To proceed, first write problem P1 into the following equivalent problem (problem P2): $\max_{(q_a: a \in \Theta)} \sum_{a \in \Theta} q_a \sum_{n=1}^N U_n(a)$, where q_a is the probability that channel selection profile a is adopted. Obviously, the optimal solution to problem P2 is to choose the optimal channel selection profile with probability one. It is known from Chen et al. (2010) that problem P2 can be approximated by the following convex optimization problem (problem P3): $\max_{(q_a: a \in \Theta)} \sum_{a \in \Theta} q_a \sum_{n=1}^N U_n(a) - \frac{1}{\gamma} \sum_{a \in \Theta} q_a$

$\log q_a$, where γ is the parameter that controls the approximation ratio. It can be seen that when $\gamma \rightarrow \infty$, problem P3 becomes exactly the same as problem P2. That is, when $\gamma \rightarrow \infty$, the optimal point a^* that maximizes the system throughput $\sum_{n=1}^N U_n(a)$ will be selected with probability one. A nice property of such an approximation in problem P3 is that the close-form solution can be obtained, which enables the distributed algorithm design later. More specifically, by the KKT condition (Boyd and Vandenberghe 2004), the optimal solution to problem P3 can be derived as

$$q_a^* = \frac{\exp\left(\gamma \sum_{n=1}^N U_n(a)\right)}{\sum_{a' \in \Theta} \exp\left(\gamma \sum_{n=1}^N U_n(a')\right)}.$$

Similarly to the spatial adaptive play in Young (2001) and Gibbs sampling in Kauffmann et al. (2007), a cooperative AP channel selection algorithm is designed in Chen and Huang (2013) by carefully coordinating APs' asynchronous channel selection updates to form a discrete-time Markov chain (with the system state as the channel selection profile a of all APs). Since each AP will be selected to update with a probability of $\frac{1}{N}$ and the selected AP will randomly choose a channel with a probability proportional to $\exp\left(\gamma \sum_{n=1}^N U_n(a)\right)$, then if $a' \in \Lambda_a$, the probability that the Markov chain transits from state a to a' is given as $q_{a,a'} = \frac{1}{N} \frac{\exp\left(\gamma \sum_{n=1}^N U_n(a'_n, a_{-n})\right)}{\sum_{a' \in \mathcal{M}_n} \exp\left(\gamma \sum_{n=1}^N U_n(a', a_{-n})\right)}$.

Otherwise, it holds that $q_{a,a'} = 0$. It is shown in Chen and Huang (2013) that the cooperative AP channel selection algorithm induces a time-reversible Markov chain with the unique stationary distribution as given above.

The social optimal point that maximizes the system-wide throughput can be approached by setting $\gamma \rightarrow \infty$ in the cooperative AP channel selection algorithm. However, in practice only a finite value of γ can be implemented such that $\exp\left(\gamma \sum_{n=1}^N U_n(a)\right)$ does not exceed the range of the largest predefined real number on a computer. Let $\bar{S} = \sum_{a \in \Theta} q_a^* \sum_{n=1}^N U_n(a)$ be the expected potential by the proposed algorithm and $S^* = \max_{a \in \Theta} \sum_{n=1}^N U_n(a)$ be the global optimal

potential. It is shown in Chen and Huang (2013) that, when a large enough γ is adopted, the performance gap between $\bar{S}$ and S^* is very small, thus achieving efficiency approximately. For the cooperative AP channel selection algorithm, it holds that $0 \leq S^* - \bar{S} \leq \frac{1}{\gamma} \ln |\Theta|$, where $|\Theta|$ denotes the number of feasible channel selection profiles of all APs.

Synonyms

Beamforming; Cognitive radio; Physical layer security; RF-based energy harvest

Definition

- Cognitive radio (CR) paradigm is an innovative solution to conciliate the existing conflict between the ever-increasing spectrum demand and the inefficient spectrum utilization by enabling a dynamic spectrum access (DSA) in cellular networks.
- Energy harvest (EH)-based radio frequency (RF) is a promising technique to prolong the low-energy devices in the fifth generation (5G) cellular networks.
- Physical layer (PHY) security is a promising mechanism to provide flexible secure communications without the perfect secret key management and distribution.

Historical Background

With the wide usage of wireless communication technologies, wireless devices consume the huge energy to support the escalating data rate and ubiquitous wireless services. However, the huge energy consumption might affect the lifetime of the wireless devices, especially for low-energy devices in cellular networks (Krikidis et al. 2014). Therefore, it is important to find a way to provide enough energy for the wireless devices for supporting the high-quality communication without increasing the dimension of the battery. Since the RF signal is capable to carry information and energy at the same time, in practice (Krikidis et al. 2014; Ding et al. 2015; Lu et al. 2015), energy harvesting at the receivers can be enhanced by increasing the energy of the information-carrying signal. However, the high-powered signals have a higher probability to be eavesdropped due to a higher potential for information leakage. As a consequence, secure communication with energy transfer has been recognized as a crucial issue in cellular networks.

Based on the benefit of PHY security (Wyner 1975), the concept of secure communication in energy harvesting systems has been recently developed in cellular networks (Liu et al. 2014; Shi et al. 2015; Ng et al. 2014; Yuan and Ding 2018). The secrecy performance was investigated based on the assumption that the base station has perfect channel state information (CSI) at the beginning of each scheduling slot (Ng et al. 2014; Shi et al. 2015). With perfect CSI, the base station can design the optimal resource allocation algorithm to efficiently balance the secrecy performance and harvested energy. However, the perfect CSI obtained at the base station reduces spectral efficiency due to a large amount of CSI feedback and channel estimations. Compared to the works assuming the availability of perfect CSI (e.g., Ng et al. 2014; Shi et al. 2015), the works in Ng et al. (2014), Wang and Wang (2015), and Yuan and Ding (2018) propose imperfect CSI available at the base station. In Ng et al. (2014) and Wang and Wang (2015), a deterministic CSI error model was adopted to

investigate the secrecy performance. In addition, the work in Yuan and Ding (2018) investigates the system security by considering a probabilistic CSI error model, which the channel error satisfies the Gaussian distribution.

This entry takes the work in Yuan and Ding (2018) as an example to investigate the secrecy performance of energy transfer systems in the cellular network under the imperfect CSI model. Then, some promising open problems in this area will be discussed.

Throughout this entry, matrices and vectors are denoted by boldface capital letters and lowercase letters, respectively. $\mathbf{A}^H$, $\text{Tr}(\mathbf{A})$, and $|\mathbf{A}|$ represent Hermitian (conjugate) transpose, trace, and determinant of a matrix $\mathbf{A}$, respectively. $\mathbf{A} \succeq \mathbf{0}$ ($\mathbf{A} \succ \mathbf{0}$) indicates that $\mathbf{A}$ is a Hermitian positive semi-definite (definite) matrix. $\text{vec}(\mathbf{A})$ is vectorization of matrix $\mathbf{A}$. $\mathbf{I}$ and $(\cdot)^{-1}$ denote an identity matrix and the inverse of a matrix, respectively. $[\cdot]^+$ denotes $\max\{x, 0\}$ and $\otimes$ is the Kronecker product. $\|\cdot\|_2$ and $\|\cdot\|_F$ represent the Euclidean norm and the Frobenius norm, respectively. $\Re\{\cdot\}$ extracts the real part from a vector. $\mathcal{CN}(\mathbf{u}, \mathbf{\Sigma})$ denotes the distribution of a circularly symmetric complex Gaussian vector with mean vector $\mathbf{u}$ and covariance matrix $\mathbf{\Sigma}$, and $\sim$ means “distributed as”. $\mathbb{C}^{x \times y}$ is the set of complex $x \times y$ matrix, and $\Pr\{\cdot\}$ is the probability of an event.

Key Applications

System Model

Consider an underlay cognitive MIMO scenario which consists of a secondary base station (SBS), $M + 1$ secondary receivers (SU), and K primary receivers (PU). The SBS, the SUs, and the PUs are equipped with N_t antennas, N_s antennas, and N_p antennas, respectively. The channels from the SBS to all the receivers are assumed to undergo quasi-static block fading. It is assumed that SUs are the low-energy devices in cellular networks. Hence, in order to prolong the lifetime of the SUs, it is assumed that only one SU can be acted as the information receivers (IR) to decode information and other M SUs are acted as the energy receiver (ER) to harvest and store energy for

future use. However, if ERs are malicious, they may attempt to eavesdrop the information rather than to harvest energy since they are deployed in the same range of service coverage. To protect the received information by the desired receiver, secure communication should be considered by regarding ERs as the potential eavesdroppers and regarding PUs as the friendly users. The SBS sends the coded confidential signal and artificial noise (AN) signal to all the receivers, denoted by $\mathbf{x} = \mathbf{s} + \mathbf{v}$, where $\mathbf{s} \in \mathbb{C}^{N_t \times 1}$ and $\mathbf{v} \in \mathbb{C}^{N_t \times 1}$. It is assumed that $\mathbf{s} \sim \mathcal{CN}(\mathbf{0}, \mathbf{Q})$ with $\mathbf{Q} \succeq \mathbf{0}$ and $\mathbf{v} \sim \mathcal{CN}(\mathbf{0}, \mathbf{V})$ with $\mathbf{V} \succeq \mathbf{0}$. The signals received at the IR, the m th ER, and the k th PU can be given, respectively

$$\mathbf{y} = \mathbf{H}^H \mathbf{x} + \mathbf{n}, \quad (1a)$$

$$\mathbf{y}_k = \mathbf{G}_k^H \mathbf{x} + \mathbf{n}_k, k \in K, \quad (1b)$$

$$\mathbf{y}_m = \mathbf{H}_m^H \mathbf{x} + \mathbf{n}_m, m \in M, \quad (1c)$$

where $\mathbf{H} \in \mathbb{C}^{N_t \times N_s}$, $\mathbf{G}_k \in \mathbb{C}^{N_t \times N_p}$, and $\mathbf{H}_m \in \mathbb{C}^{N_t \times N_s}$ are the channel matrices between the SBS and the IR, the k th PU, and the m th ER, respectively. $\mathbf{n}$, $\mathbf{n}_k$, and $\mathbf{n}_m$ are assumed to be independent and identically distributed (i.i.d.) complex Gaussian noise with zero mean and unit variance. Therefore, the maximum achievable secrecy rate between the SBS and the IR can be expressed as (Bloch et al. 2008)

$$R_s = \left[C_{IR} - \max_{m \in M} C_m \right]^+ \quad (2)$$

where $[x]^+$ denotes $\max(0, x)$; $C_{IR} = \log |\mathbf{H}^H(\mathbf{Q} + \mathbf{V})\mathbf{H} + \mathbf{I}| - \log |\mathbf{H}^H\mathbf{V}\mathbf{H} + \mathbf{I}|$; $C_m = \log |\mathbf{H}_m^H(\mathbf{Q} + \mathbf{V})\mathbf{H}_m + \mathbf{I}| - \log |\mathbf{H}_m^H\mathbf{V}\mathbf{H}_m + \mathbf{I}|$. Note that the perfect secrecy rate is achieved when the IR can correctly decode the confidential information at R_s bits per channel use, while all ER can retrieve almost nothing about the secret message. Since the secondary system and the primary system share the same spectrum resource in the underlay CR network, the interference at the k th PU caused by the SBS is given by

$$I_k = \text{Tr}(\mathbf{G}_k^H(\mathbf{Q} + \mathbf{V})\mathbf{G}_k), k \in K. \quad (3)$$

In this entry, the linear energy harvest model is assumed to be applied at each ER. Thus, the harvested energy at the m th ER is given by

$$E_m = \xi_m \text{Tr}(\mathbf{H}_m^H (\mathbf{Q} + \mathbf{V}) \mathbf{H}_m), \quad m \in M \quad (4)$$

where $\xi_m \in (0, 1]$ is the energy conversion efficiency at the m th ER.

Secure Communication Design with Partial Imperfect CSI

In this section, the secrecy performance of the energy-constrained cellular network will be investigated under the partial CSI model which is assumed that perfect CSI for the SBS-to-IR channel and imperfect CSI for the SBS-to-ER channels and the SBS-to-PU channels are available at the SBS during the whole transmission period. To capture the effect caused by imperfect CSI, a probabilistic model will be adopted for modeling the resulting CSI uncertainty.

Probabilistic CSI Error Model

In a probabilistic CSI error model, CSI error is random and follows a certain distribution (Wang et al. 2014). Specifically, CSI error satisfies the complex Gaussian distribution. Accordingly, the actual channel between the SBS and the m th ER as well as the k th PU can be modeled as, respectively

$$\begin{aligned} \mathbf{H}_m &= \hat{\mathbf{H}}_m + \Delta \mathbf{H}_m, \quad m \in M, \\ \mathbf{G}_k &= \hat{\mathbf{G}}_k + \Delta \mathbf{G}_k, \quad k \in K, \end{aligned} \quad (5)$$

where $\hat{\mathbf{H}}_m \in \mathbb{C}^{N_t \times N_s}$ and $\hat{\mathbf{G}}_k \in \mathbb{C}^{N_t \times N_p}$ denote the channel estimation of the m th ER and the k th PU available at the SBS, respectively. $\Delta \mathbf{H}_m$ and $\Delta \mathbf{G}_k$ represent the associated unknown channel uncertainty. Specifically, $\mathbf{e}_{h,m} = \text{vec}(\Delta \mathbf{H}_m) \sim \mathcal{CN}(0, \mathbf{C}_m)$ with $\mathbf{C}_m \succeq \mathbf{0}$ and $\mathbf{e}_{g,k} = \text{vec}(\Delta \mathbf{G}_k) \sim \mathcal{CN}(0, \mathbf{D}_k)$ with $\mathbf{D}_k \succeq \mathbf{0}$.

Efficient Beamforming Design

Efficient beamforming design has been demonstrated to have a significant impact on the security performance under the perfect CSI scenarios

(Ng et al. 2014; Shi et al. 2015). Motivated by this, a robust outage design will be proposed to maximize the secrecy rate in (2) under the transmit power constraint and the outage constraints for EH and interference power. Therefore, an outage-constrained secrecy rate maximization (OC-SRM) problem is formulated as follows:

$$(P1) : \max_{\mathbf{Q}, \mathbf{V}, R} R \quad (6a)$$

$$s.t. \quad \Pr\{\min_{m \in M} \{C_{IR} - C_m\} \geq R\} \geq 1 - \rho, \quad \forall m, \quad (6b)$$

$$\Pr\{\xi \text{Tr}(\mathbf{H}_m^H (\mathbf{Q} + \mathbf{V}) \mathbf{H}_m) \geq \eta_m\} \geq 1 - \rho_m, \quad \forall m, \quad (6c)$$

$$\Pr\{\text{Tr}(\mathbf{G}_k^H (\mathbf{Q} + \mathbf{V}) \mathbf{G}_k) \leq \Gamma_k\} \geq 1 - \rho_k, \quad \forall k, \quad (6d)$$

$$\text{Tr}(\mathbf{Q} + \mathbf{V}) \leq P, \quad \mathbf{Q} \succeq \mathbf{0}, \quad \mathbf{V} \succeq \mathbf{0}, \quad (6e)$$

where η_m and Γ_k denote the minimum required power transfer to the m th ER and the maximum interference power to the k th PU, respectively. P is the maximum transmit power supply at the SBS. ρ , ρ_m , and ρ_k denote the maximum outage probability associated with the secrecy rate, the EH of the m th ER, and the interference power of the k th PU, respectively. Constraints in (6e) guarantee matrices $\mathbf{Q}$ and $\mathbf{V}$ to be positive semi-definite Hermitian matrices. This outage-constrained problem (P1) emphasizes service fidelity. Specifically, under CSI errors, a feasible solution to (P1) guarantees that the IR can still reliably achieve R secrecy message at least $(1 - \rho)$ and the m th ER can harvest η_m energy of the time.

Remark 1 The considered OC-SRM problem may be infeasible when the EH and interference power requirements are stringent and/or the channels are in unfavorable conditions. Without loss of generality, in the rest of this entry, it is assumed that P1 is always feasible for studying the efficient beamforming design.

Problem (P1) is non-convex and very challenging to solve (Boyd and Vandenberghe 2004). The main obstacle to solve P1 lies in the outage

probability constraints (6b), (6c), and (6d), which do not have the tractable closed-form expression. In the following, an efficient algorithm will be proposed to derive the safe approximation to (P1). The “safe” means that the obtained feasible solution always satisfies the outage constraints (6b), (6c), and (6d). According to the challenge 1 proposed in Wang et al. (2014), the idea is to find out the upper bound f of each outage constraint, which satisfies the following condition:

$$\Pr\{\mathbf{e}^H \mathbf{Q} \mathbf{e} + 2\Re\{\mathbf{e}^H \mathbf{r}\} + s < 0\} \leq f(\mathbf{Q}, \mathbf{r}, s), \quad (7)$$

where $\mathbf{e} \sim \mathcal{CN}(\mathbf{0}, \mathbf{I})$. In order to solve the outage secrecy rate constraint in (6b), the following mutual information approximation at the low signal-to-noise ratio (SNR) needs to be considered (Verdú 2002; Wang and Palomar 2009):

$$\log |\mathbf{I} + \frac{1}{\sigma^2} \mathbf{H} \mathbf{Q} \mathbf{H}^H| = \frac{1}{\sigma^2} \text{Tr}\{\mathbf{H} \mathbf{Q} \mathbf{H}^H\} + \mathcal{O}(\frac{1}{\sigma^2} \|\mathbf{H} \mathbf{Q} \mathbf{H}^H\|). \quad (8)$$

Beside this approximation, the following lemma also needs to be used.

Lemma 1 [Jose et al. 2011, Lemma 2:] Define a positive matrix $\mathbf{E} \succ \mathbf{0}$, $\mathbf{E} \in \mathbb{C}^{N \times N}$ with integer N , there exist a function, $v(\mathbf{S}, \mathbf{E}) = -\text{Tr}(\mathbf{S}\mathbf{E}) + \ln |\mathbf{S}| + N$, satisfies the following equation:

$$\ln |\mathbf{E}^{-1}| = \max_{\mathbf{S} \in \mathbb{C}^{N \times N}, \mathbf{S} \succeq \mathbf{0}} v(\mathbf{S}, \mathbf{E}) \quad (9)$$

and the optimal solution to the right-hand side of (9) is $\mathbf{S}^* = \mathbf{E}^{-1}$.

Based on the low SNR approximation and Lemma 1, the secrecy rate expression can be reformulated to the same form in the left-hand side of inequality in (7).

Lemma 2 [Wang et al. 2014, Lemma 1:] Consider the following outage constraint

$$f(\mathbf{A}, \mathbf{u}, c) \Leftrightarrow \Pr\{\mathbf{x}^H \mathbf{A} \mathbf{x} + 2\text{Re}\{\mathbf{x}^H \mathbf{u}\} + c \geq 0\} \geq 1 - \rho, \quad (10)$$

where $\mathbf{A} \in \mathbb{C}^{N \times N}$ is a complex Hermitian matrix, $\mathbf{a} \in \mathbb{C}^{N \times 1}$, $\mathbf{x} \sim \mathcal{CN}(\mathbf{0}, \mathbf{I})$ and fixed $\rho \in (0, 1]$. With any slack variables λ and μ , the outage constraint can be equivalently transformed into the following three inequalities:

$$\begin{cases} \text{Tr}(\mathbf{A}) - \sqrt{-2 \ln(\rho)} \lambda + \ln(\rho) \mu + c \geq 0, \\ \left\| \begin{bmatrix} \text{vec}(\mathbf{A}) \\ \sqrt{2} \mathbf{u} \end{bmatrix} \right\| \leq \lambda, \\ \mu \mathbf{I}_N + \mathbf{A} \succeq \mathbf{0}, \quad \mu \geq 0. \end{cases} \quad (11)$$

and the optimal solution to the right-hand side of (9) is $\mathbf{S}^* = \mathbf{E}^{-1}$.

By applying Lemma 2 and setting $\mathbf{e}_m = \mathbf{C}_m^{\frac{1}{2}} \mathbf{v}_m$, $\mathbf{e}_k = \mathbf{D}_k^{\frac{1}{2}} \mathbf{x}_k$, all outage constraints in problem (P1) can be converted into the deterministic constraints. Therefore, the safe approximation problem of (P1) is given by

$$\text{(P1-APP)} : \max_{\mathbf{Q}, \mathbf{V}, \mathbf{S}, \mathbf{S}_m, R, \lambda_m, \mu_m, \alpha_m, \beta_m, v_k, \omega_k} R \quad (12a)$$

$$\text{s.t. } \text{Tr}(\mathbf{C}_m^{\frac{1}{2}} \mathbf{\Theta}_m \mathbf{C}_m^{\frac{1}{2}}) + \sqrt{-2 \ln(\rho)} \lambda_m - \ln(\rho) \mu_m + c_m \leq 0, \quad \forall m, \quad (12b)$$

$$\text{Tr}(\mathbf{C}_m^{\frac{1}{2}} \mathbf{\Xi} \mathbf{C}_m^{\frac{1}{2}}) - \sqrt{-2 \ln(\rho_m)} \alpha_m + \ln(\rho_m) \beta_m + \widehat{\mathbf{h}}_m^H \mathbf{\Xi} \widehat{\mathbf{h}}_m - \frac{\eta_m}{\xi} \geq 0, \quad \forall m, \quad (12c)$$

$$\text{Tr}(\mathbf{D}_k^{\frac{1}{2}} \mathbf{\Xi} \mathbf{D}_k^{\frac{1}{2}}) + \sqrt{-2 \ln(\rho_k)} v_k - \ln(\rho_k) \omega_k + \widehat{\mathbf{g}}_k^H \mathbf{\Xi} \widehat{\mathbf{g}}_k - \Gamma_k \leq 0, \quad \forall k, \quad (12d)$$

$$\left\| \begin{bmatrix} \text{vec}(\mathbf{C}_m^{\frac{1}{2}} \mathbf{\Theta}_m \mathbf{C}_m^{\frac{1}{2}}) \\ \sqrt{2} \mathbf{C}_m^{\frac{1}{2}} \mathbf{\Theta}_m \mathbf{h}_m \end{bmatrix} \right\| \leq \lambda_m, \quad \forall m, \quad (12e)$$

$$\left\| \begin{bmatrix} \text{vec}(\mathbf{C}_m^{\frac{1}{2}} \mathbf{\Xi} \mathbf{C}_m^{\frac{1}{2}}) \\ \sqrt{2} \mathbf{C}_m^{\frac{1}{2}} \mathbf{\Xi} \hat{\mathbf{h}}_m \end{bmatrix} \right\| \leq \alpha_m, \quad \forall_m, \quad (13a)$$

$$\left\| \begin{bmatrix} \text{vec}(\mathbf{D}_k^{\frac{1}{2}} \mathbf{\Xi} \mathbf{D}_k^{\frac{1}{2}}) \\ \sqrt{2} \mathbf{C}_m^{\frac{1}{2}} \mathbf{\Xi} \hat{\mathbf{g}}_k \end{bmatrix} \right\| \leq \nu_k, \quad \forall_k, \quad (13b)$$

$$\mu_m \mathbf{I}_{N_t \times N_s} - \mathbf{C}_m^{\frac{1}{2}} \mathbf{\Theta}_m \mathbf{C}_m^{\frac{1}{2}} \succeq \mathbf{0}, \quad \mu_m \geq 0, \quad \forall_m, \quad (13c)$$

$$\beta_m \mathbf{I}_{N_t \times N_s} + \mathbf{C}_m^{\frac{1}{2}} \mathbf{\Xi} \mathbf{C}_m^{\frac{1}{2}} \succeq \mathbf{0}, \quad \beta_m \geq 0, \quad \forall_m, \quad (13d)$$

$$\omega_k \mathbf{I}_{N_t \times N_p} - \mathbf{D}_k^{\frac{1}{2}} \mathbf{\Xi} \mathbf{D}_k^{\frac{1}{2}} \succeq \mathbf{0}, \quad \omega_k \geq 0, \quad \forall_k, \quad (13e)$$

$$\mathbf{S} \succeq \mathbf{0}, \mathbf{S}_m \succeq \mathbf{0}, \quad (6e), \quad (13f)$$

E

where $\hat{\mathbf{h}}_m = \text{vec}(\hat{\mathbf{H}}_m)$, $\hat{\mathbf{g}}_k = \text{vec}(\hat{\mathbf{G}}_k)$, $\mathbf{\Theta}_m = (\mathbf{S}_m^T \otimes (\mathbf{Q} + \mathbf{V}) - \mathbf{I}_{N_t} \otimes \mathbf{V})$, $c_m = \hat{\mathbf{h}}_m^H \mathbf{\Theta}_m \hat{\mathbf{h}}_m - \text{Tr}(\mathbf{H}^H (\mathbf{Q} + \mathbf{V}) \mathbf{H}) + \text{Tr}(\mathbf{S}(\mathbf{H}^H \mathbf{V} \mathbf{H} + \mathbf{I})) - \ln |\mathbf{S}| - 2N_s + \text{Tr}(\mathbf{S}_m) - \ln |\mathbf{S}_m| + R$, and $\mathbf{\Xi} = \mathbf{I} \otimes (\mathbf{Q} + \mathbf{V})$.

Note that problem (P1-APP) is non-convex w.r.t. all the variables jointly (Boyd and Vandenberghe 2004). However, (P1-APP) becomes convex when fixing either $(\mathbf{Q}, \mathbf{V})$ or $(\mathbf{S}, \mathbf{S}_m)$. Hence, an alternating optimization (AO) algorithm is proposed to optimize all variables in (P1-APP) (Schubert and Boche 2004). Specifically, problem (P1-APP) becomes a convex problem by fixing $(\mathbf{S}, \mathbf{S}_m)$. Then, the same operation can be considered to optimize $(\mathbf{S}, \mathbf{S}_m)$. The summarization of the proposed AO algorithm is presented in the following:

-
- 1 Initialize
 $n = 1, \varepsilon > 0, \mathbf{S}^0 = \mathbf{I}, \mathbf{S}_m^0 = \mathbf{I}, m = 1, \dots, M$.
 - 2 At the l th iteration
 - a) Solve (P1-APP) with fixed $\mathbf{S} = \mathbf{S}^{l-1}$ and $\mathbf{S}_m = \mathbf{S}_m^{l-1}$ to obtain $(\mathbf{Q}^{l-1}, \mathbf{V}^{l-1})$.
 - b) Solve (P1-APP) with fixed $\mathbf{Q} = \mathbf{Q}^{l-1}$ and $\mathbf{V} = \mathbf{V}^{l-1}$ to obtain $(\mathbf{S}^l, \mathbf{S}_m^l, R^l)$.
 - 3 Update $l = l + 1$ and repeat step (2) until the optimal value is found.
-

It notes that the convex problems in step a) and b) can be efficiently solved by using off-the-shelf solver, e.g., CVX (Grant and Boyd 2011). Moreover, the optimal solutions generated at the $l - 1$ th iteration are also the

feasible values at the l th iteration. For this reason, the proposed AO algorithm generates a nondecreasing sequence of the secrecy rate and converges to a stationary point. In addition, the smaller predefined accuracy is, the more iterative steps are need. Hence, the time of solving the proposed algorithm can be roughly estimated as the time of solving the two subproblems multiplies the number of iterations.

Secure Communication Design with Full Imperfect CSI

Although the transmitter can obtain perfect CSI of the user through measuring the uplink pilots in the handshaking/beacon signals via channel reciprocity, CSI of the user might not be perfectly obtained in some special communication scenarios. Therefore, in this section, a more general channel model will be introduced in which it is assumed that imperfect CSI of the SBS-to-IR channel are available at the SBS during the whole transmission period.

Probabilistic CSI Error Model

In the above section, the error model of the SBS-to- m th ER link and the SBS-to- k th PU link has been derived. Therefore, the actual channel between the SBS and the IR can be modeled as

$$\mathbf{H} = \hat{\mathbf{H}} + \Delta \mathbf{E}, \quad (14)$$

where $\hat{\mathbf{H}} \in \mathbb{C}^{N_t \times N_s}$ is the channel estimate of the IR; $\Delta \mathbf{E}$ denote the associated unknown channel uncertainty; and $\mathbf{e} = \text{vec}(\Delta \mathbf{E}) \sim \mathcal{CN}(0, \mathbf{Z})$ with $\mathbf{Z} \succeq \mathbf{0}$.

Efficient Beamforming Design

In this subsection, the efficient beamforming is designed based on the practical channel uncertainty model. In this case, the OC-SRM problem is the same to (P1), but the secrecy rate expression in (2) needs to be carefully reformulated since channel errors are included in both rate expressions. Based on the low SNR approximation in (8) and Lemma 1, the secrecy outage constraint (6b) can be approximated to the following constraint by setting $\mathbf{e} = \mathbf{Z}^{\frac{1}{2}} \mathbf{v}$:

$$\begin{aligned} & \Pr \left\{ [\mathbf{v}^H \mathbf{v}_m^H] \begin{bmatrix} \mathbf{Z}^{\frac{1}{2}} \boldsymbol{\varpi} \mathbf{Z}^{\frac{1}{2}} & \mathbf{0} \\ \mathbf{0} & \mathbf{C}_m^{\frac{1}{2}} \boldsymbol{\Psi}_m \mathbf{C}_m^{\frac{1}{2}} \end{bmatrix} [\mathbf{v}^H \mathbf{v}_m^H]^H \right. \\ & + 2\Re \left([\mathbf{v}^H \mathbf{v}_m^H] \begin{bmatrix} \mathbf{Z}^{\frac{1}{2}} \boldsymbol{\varpi} & \mathbf{0} \\ \mathbf{0} & \mathbf{C}_m^{\frac{1}{2}} \boldsymbol{\Psi}_m \end{bmatrix} [\hat{\mathbf{h}}^H \hat{\mathbf{h}}_m^H]^H \right) \\ & \left. + [\hat{\mathbf{h}}^H \hat{\mathbf{h}}_m^H] \begin{bmatrix} \boldsymbol{\varpi} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{\Psi}_m \end{bmatrix} [\hat{\mathbf{h}}^H \hat{\mathbf{h}}_m^H]^H - c_m \leq 0 \right\} \geq 1 - \rho, \end{aligned} \quad (15)$$

where $\hat{\mathbf{h}} = \text{vec}(\hat{\mathbf{H}})$, $\boldsymbol{\varpi} = \mathbf{S}^T \otimes \mathbf{V} - \mathbf{I}_{N_t} \otimes (\mathbf{Q} + \mathbf{V})$, $\boldsymbol{\Psi}_m = \mathbf{S}_m^T \otimes (\mathbf{Q} + \mathbf{V}) - \mathbf{I}_{N_t} \otimes \mathbf{V}$, and $c_m = -\text{Tr}(\mathbf{S}) + \ln |\mathbf{S}| - \text{Tr}(\mathbf{S}_m) + \ln |\mathbf{S}_m| - R$. The outage constraint has the similar form with (10); therefore, the outage constraint (15) can be equivalently converted to the following deterministic constraint by applying Lemma 2:

$$\begin{cases} \text{Tr}(\mathbf{A}_{s,m}) + \sqrt{-2 \ln(\rho) \theta_{s,m} - \ln(\rho) \delta_{d,m} + \sigma_{s,m}} \leq 0, \\ \left\| \begin{bmatrix} \text{vec}(\mathbf{A}_{s,m}) \\ \sqrt{2} \mathbf{B}_{s,m} \end{bmatrix} \right\| \leq \theta_{s,m}, \\ \delta_{s,m} \mathbf{I}_{N_t \times N_s} - \mathbf{A}_{s,m} \succeq \mathbf{0}, \quad \delta_{s,m} \geq 0, \end{cases} \quad (16)$$

$$\begin{aligned} \text{where } \mathbf{A}_{s,m} &= \begin{bmatrix} \mathbf{Z}^{\frac{1}{2}} \boldsymbol{\varpi} \mathbf{Z}^{\frac{1}{2}} & \mathbf{0} \\ \mathbf{0} & \mathbf{C}_m^{\frac{1}{2}} \boldsymbol{\Psi}_m \mathbf{C}_m^{\frac{1}{2}} \end{bmatrix}, \\ \mathbf{B}_{s,m} &= \begin{bmatrix} \mathbf{Z}^{\frac{1}{2}} \boldsymbol{\varpi} & \mathbf{0} \\ \mathbf{0} & \mathbf{C}_m^{\frac{1}{2}} \boldsymbol{\Psi}_m \end{bmatrix} [\hat{\mathbf{h}}^H \hat{\mathbf{h}}_m^H]^H, \quad \sigma_{s,m} = \end{aligned}$$

$[\hat{\mathbf{h}}^H \hat{\mathbf{h}}_m^H] \begin{bmatrix} \boldsymbol{\varpi} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{\Psi}_m \end{bmatrix} [\hat{\mathbf{h}}^H \hat{\mathbf{h}}_m^H]^H - c_m$, $\mathbf{v}_{s,m} = [\mathbf{v}^H \mathbf{v}_m^H]^H$. The EH and interference power outage constraints based on the full uncertainty model are the same as that of partial model. Hence, the OC-SRM problem based on the full uncertainty model is reformulated by

$$\begin{aligned} \text{(P2): } & \max_{\mathbf{Q}, \mathbf{V}, \mathbf{S}, \mathbf{S}_m, R, \delta_{s,m}, \theta_{s,m}, \alpha_m, \beta_m, \nu_k, \omega_k} R \\ \text{s.t. } & \text{(12c), (12d), (13a), (13b), (13d), (13f), (16), (17)} \end{aligned}$$

Similar to (P1-APP), problem (P2) is non-convex due to the coupled variables. Therefore, the AO algorithm proposed for solving (P1-APP) also can be used to solve (P2).

Numerical Results

In this section, the system performance of the considered security cellular network under the imperfect CSI model will be evaluated via computer simulation results. All estimated channels are randomly generated following an i.i.d. complex Gaussian distribution with zero mean and unit variance. The number of antenna at the SBS sets to 4, $N_t = 4$, and at the receivers sets to 3, $N_s = N_p = 3$. In addition, the number of the ER and the PU is set to 3, $M = K = 3$. The EH requirement and the interference power tolerance are considered as -5 and 5 dBm, respectively. The maximum outage is $\rho_s = \rho_m = \rho_k = \rho = 0.01$, $\forall_m$, $\forall_k$, and the error variance is $\mathbf{Z} = \mathbf{C}_m = \mathbf{D}_k = \sigma^2 \mathbf{I}$, $\forall_m$, $\forall_k$.

Benchmark Schemes

- (1) *Perfect CSI Scheme*: The perfect CSI scheme is taken as one benchmark to provide an upper-bound secrecy performance. In this scheme, the SBS knows the exact CSI of all links.
- (2) *Non-robust Scheme*: To show the benefits of the proposed robust design, the secrecy performance of the non-robust design is taken as the second benchmark scheme, in which the SBS does not spend the additional transmit power to overcome the

effects caused by the channel errors. In this case, the actual channels included error that can be randomly generated based on their distribution, i.e., $\text{vec}(\mathbf{H}) \sim \mathcal{CN}(\text{vec}(\hat{\mathbf{H}}), \mathbf{Z})$, $\text{vec}(\mathbf{H}_m) \sim \mathcal{CN}(\text{vec}(\hat{\mathbf{H}}_m), \mathbf{C}_m)$, $\forall m$, $\text{vec}(\mathbf{G}_k) \sim \mathcal{CN}(\text{vec}(\hat{\mathbf{G}}_k), \mathbf{D}_k)$, $\forall k$.

- (3) *Worst-Case Scheme*: To show the benefits of the proposed outage design, the worst-case design is taken as the third benchmark scheme, in which the deterministic CSI uncertainty model is considered to capture the effects caused by the channel errors. In order to have a fair comparison with the proposed outage design scheme, the error bound used in the worst-case design is generated by $\varepsilon = \sqrt{\frac{\sigma^2 F_{2N_t \times N}^{-1}(1-\rho)}{2}}$, where $F_{2N_t \times N}^{-1}(\cdot)$ denotes the inverse cumulative distribution function (CDF) of the chi-square distribution with $2N_t \times N$ degrees of freedom (Wang et al. 2014).

Secrecy Performance

The secrecy performance of the energy-constrained cellular network is shown under the partial imperfect CSI model. In Figs. 1 and 2, the secrecy performance of the proposed outage scheme is compared with the benchmark

schemes defined previously under the different transmit power P and error variance σ^2 . From these figures, one can observe that the proposed outage scheme with the efficient beamforming design outperforms the comparable schemes, i.e., non-robust scheme and worst-case scheme. As shown in Fig. 1, the secrecy rates of all the schemes increase with respect to the transmit power P and finally become saturate, which is due to the interference power constraint to the PU. Moreover, the performance generated by the proposed outage design is closer to the perfect CSI scheme compared with the other two schemes, so the proposed outage design can significantly improve the secrecy performance for the imperfect CSI models. From Fig. 2, the secrecy performance of all the schemes is affected by the channel estimation error. The proposed outage design outperforms the other two benchmark schemes, and the performance gap becomes large as error variance increases. Moreover, the secrecy performance of strict interference power tolerance ($I = -6\text{ dB}$) is worse than that of the relaxed tolerance ($I = 2\text{ dB}$).

The secrecy performance of the energy-constrained cellular network is focused based on the full channel uncertainty model. In Figs. 3

Efficient Beamforming Design for Cellular Networks with Energy-Constrained Devices, Fig. 1

The secrecy rate of the different methods versus the transmit power based on the partial uncertainty model with $I = -5\text{ dB}$, $\sigma^2 = 0.001$, and $\eta_m = \eta = 5\text{ dBm}$

Efficient Beamforming Design for Cellular Networks with Energy-Constrained Devices, Fig. 2

The secrecy rate versus error variance σ^2 for the different interference power based on the PCU model with $P = 5$ dB, $\eta_m = \eta = 5$ dBm

Efficient Beamforming Design for Cellular Networks with Energy-Constrained Devices, Fig. 3

The secrecy rate of the different methods versus the transmit power based on the full uncertainty model with $I = -5$ dB, $\sigma^2 = 0.001$, $\eta_m = \eta = 5$ dBm

and 4, the secrecy performance of the proposed outage scheme is compared with the benchmark schemes under the different transmit power P and error variance σ^2 . As shown in Fig. 3, the secrecy performance of all the schemes has a significant improvement with the sufficient transmit power supply, especially for the outage scheme. This implies that the proposed outage scheme is capable to generate the efficient

beamforming to enhance the system security. The results in Fig. 4 indicate that the secrecy rates of all the schemes have the same degradation trend but the proposed outage scheme still can achieve the better performance compared with the other two schemes. The reason is that the outage scheme can efficiently utilize the transmit power to overcome the error estimation effects.

Efficient Beamforming Design for Cellular Networks with Energy-Constrained Devices, Fig. 4

The secrecy rate versus error variance σ^2 for the different interference power based on the full uncertainty model with $P = 5$ dB, $\eta_m = \eta = 5$ dBm

Conclusion

This entry has provided a fundamental analysis for investigating the secrecy performance of the underlay energy-constrained cellular network with imperfect CSI. To capture the effects of the channel uncertainty, a probabilistic CSI error model was proposed. Then, based on the proposed channel uncertainty models, the OR-SRM problem was formulated to design the efficient resource allocation in order to improve the system security. The proposed optimization problem was a non-convex problem due to the outage constraints. By applying the transformation and approximation, the non-convex problem was decoupled to two conic convex problems. Then, an AO algorithm was proposed to iteratively solve these two convex problems. The considered outage design was demonstrated to outperform the worst-case and non-robust design in terms of the secrecy rate via numerical results under the imperfect CSI model in the cellular network.

Future work of interest includes extending the considered outage design to multiple IRs to evaluate the secrecy rate and harvested energy. Furthermore, combining PHY security techniques with cryptography techniques in the higher communication protocol layers to further improve the secrecy performance in energy-constrained

cellular networks is thus another interesting problem to investigate in the future. Finally, secrecy energy efficiency (SEE) and secrecy spectral efficiency (SSE) could be studied to balance the security and energy consumption.

Introduction

The Internet of Things (IoT) is a novel paradigm which enables Internet connectivity to all kinds of objects and people (Qiu et al. 2018). Such objects, also called IoT devices, can be sensors, actuators, embedded systems, smart devices, and mobile phones. In this new paradigm, everything and everyone with a common interest can be connected, and for that reason, IoT is often called the Internet of Everything. In IoT systems, IoT devices collect data from physical systems, communicate with gateways for data aggregation, and connect to the Internet to forward the data to the cloud or edge computing devices for further processing and analysis. By connecting IoT devices to the Internet, the IoT ecosystem promises to bring improvements to our quality of lives, environment and system performance in the home, building, city, electric power grid, vehicles, transportation, logistics, healthcare, and many more. Figure 1 illustrates some of emerging IoT application scenarios. Although wireless sensor networks (WSN) are one of the main

E

Emerging Wireless Technologies for Internet of Things Applications: Opportunities and Challenges, Fig. 1
Emerging IoT application scenarios

components of IoT systems, unlike WSN devices, IoT devices are smart enough to take optimal decisions with or without minimal human intervention. According to the recent Cisco report (2018), the number of IoT devices connected to the Internet will reach 50 billion by 2020.

Different communication technologies (wired, optical, and wireless) can be used for data communications among a huge number of IoT devices and for backhaul network scenarios. Wireless technologies will be the best option to connect such IoT devices because of its benefits over wired technologies including easier installation, lower cost infrastructures, mobility support, scalability, and ease of connection. Consequently, in this work, we only focus on wireless technologies. However, traditional popular wireless technologies such as classic Bluetooth, Wi-Fi, LTE, and so on cannot adequately support the envisioned IoT communication networks because of the following reasons:

- (i) They do not have adequate power saving mechanisms to support resource-limited IoT devices.
- (ii) They are mainly designed for human-operated devices.
- (iii) They cannot support a large number of connecting devices through a single base stations or an access point.
- (iv) The frequency bands they use are not suitable for low data rate and long-range communications.
- (v) The use unsuitable wide channel bandwidth that does not support low data rate massive number of devices.

To address the above issues, many researchers, industry groups, and standardization bodies are working towards developing wireless technologies dedicated to IoT and some have already been introduced, often referred to as low power wireless technologies. Hence, it is expected that many

IoT devices would be connected through these technologies to bring people and the physical world onto the Internet.

IoT applications have diverse requirements. This means that more than one wireless technology is necessary to support these applications. Future IoT scenarios will leverage a hybrid network consisting of multiple wireless technologies. Therefore, it is necessary to define the communication requirements of emerging IoT applications so that we can determine the optimal wireless technologies that can fulfill the future IoT vision.

We summarize the main contributions of this article as follows:

- We present the communication requirements of emerging IoT applications.
- We identify wireless technologies and analyze their suitability in meeting the various IoT requirements.
- We present open issues about new research areas needed to improve wireless technologies.

The rest of this article is organized as follows. The next section presents the main communications requirements of IoT scenarios, focusing on a number of specific IoT applications. In section “[Candidate Wireless Technologies for IoT Applications](#),” we present various wireless technologies along with their characteristics. Next, we highlight the pros and cons of each wireless technology when used in IoT applications. In section “[Open Issues](#),” we the open issues to explore future research opportunities and we finally make some concluding remarks in section “[Conclusion](#).”

Communication Requirements of IoT Applications

IoT is paving the way for the emergence of a wide range of applications. In this section, we select some emerging IoT applications and discuss their

communication requirements for various IoT scenarios. IoT applications typically have following communication requirements.

- (i) *Communication latency*: The delay incurred by a particular application during data communication is called communication latency. It directly affects the usability and efficiency of IoT applications. Although latency requirements vary from one application to another, most of the IoT applications are sensitive to latency. Hence, low latency is desirable.
- (ii) *Power consumption*: In general, wireless IoT devices are powered from batteries or energy harvesting. Therefore, the power consumption for wireless IoT devices should be as low as possible.
- (iii) *Data rate*: In many IoT scenarios, most applications require low data rate although some may need a higher data rate. Usually, high data rates will depend on the network bandwidth of the underlying communication channels.
- (iv) *Range*: Wireless technologies need to operate over an adequate range to support IoT applications efficiently and they often extend their coverage using routers, gateway, or access points (AP). The range varies according to the nature of applications.
- (v) *Support for a large number of connections*: The wireless technologies in an IoT ecosystem have to support a large number IoT devices, smart devices, and people from hundreds to billions. Typically, the number of IoT devices is much higher than smartphones.
- (vi) *Mobility*: IoT devices can be either stationary or mobile. For example, there are no mobile IoT devices in smart grid applications, while smart transportation has many mobile devices.

Table 1 presents a summary of the communication requirements of IoT applications. Depending on the particular application scenario, the requirements may differ.

Emerging Wireless Technologies for Internet of Things Applications: Opportunities and Challenges, Table 1
Communication requirements for IoT applications

IoT application	Tolerable latency	Power consumption	Data rate	No. of devices	Mobility	Range
Smart Home	Medium	Low	Low	Low	Low	Short
Smart Building	Medium	Low	Low	Medium	Low	Short–medium
Smart Grid	Medium–high	Low	Low	High	Low	Long
Smart Meter	Medium–high	Low	Low	Low	No	Short
Smart Security	Low	Low	High	Medium	No	Medium
Smart Industry	Medium	Low	Variable	High	Medium	Medium
Smart Health	Low	Low	Low–medium	Medium	Medium	Short–medium
Smart Vehicle	Low	Low	Very high	Medium	Very high	Short
Smart Transportation	Low	Low	Very high	High	Very high	Medium–long
Smart City	Variable	Low	Variable	Variable	Medium	Long

Candidate Wireless Technologies for IoT Applications

In recent years, several wireless technologies have emerged in order to support many of the communication requirements of IoT applications. To choose an appropriate technology for IoT applications, we need to carefully consider the main characteristics of those technologies. In this section, we present the main wireless technologies that can be deployed for IoT applications.

Bluetooth Low Energy (BLE)

BLE is developed by Bluetooth Special Interest Group (SIG) for low power and short range applications (Harris et al. 2016). Compared with classic Bluetooth, its coverage area is 10 times higher, it reduces the communication latency by 15 times, allows multi-hop scenarios, and can be operated by transmitting power that ranges from 0.01 mW to 10 mW. These characteristics make it possible to be a potential candidate for some IoT applications. At the physical layer, BLE uses 40 channels with 2 MHz channel spacing. Among 40 channels, 3 are dedicated. One is used as an advertising channel to discover the devices. Another one is used for setting up a connection and the third one is used for broadcast transmissions. The remaining channels are used as data channels. The dedicated advertising

channels were selected to avoid interference with other wireless technologies which also operate in the 2.4 GHz band. However, the latest BLE specification to date is Bluetooth 5 after versions 4.0, 4.1 and 4.2 (<https://www.bluetooth.com/specifications/bluetooth-core-specification/bluetooth5>). The new features extend the communication range and data rate and simplify the deployment of a BLE network in IoT applications.

WiFi

WiFi becomes an everyday tool already for Internet access in our everyday lives. The WiFi standard IEEE 802.11 was first released in 1997 and many amendments were approved after that. But most of the amendments were optimized and designed for smartphones, tablets, and laptops, not for IoT devices. However, some recently approved IEEE 802.11 amendments have been designed to support different IoT applications which we describe below.

Low Power WiFi (LPW): LPW was introduced to address weaknesses such as the bandwidth, coverage range, and number of connections between traditional networks and the emerging demand for IoT applications. IEEE 802.11ah is the standard for LPW which is an amendment of IEEE 802.11 standard (Park 2015). It designs by modifying the PHY and MAC layers including new short frame formats, advanced

channel access mechanisms, and novel power management mechanisms in order to allow connectivity among IoT devices with WiFi. A new channel access mechanism called Restricted Access Window (RAW) has been introduced to minimize collision probability. Additionally, WiFi Direct is another step in WiFi's evolution that enables direct communications among devices without APs.

WhiteFi: WhiteFi introduces the use of WiFi technology within the TV white space (TVWS) spectrum. The IEEE 802.11af standard describes the use of WiFi on TVWS operation and implementation (Hassan et al. 2017). TVWS is the unused spectrum resource that is basically allocated to TV broadcasters (called primary users) that can be utilized by unlicensed devices (also called secondary users).

DSRC: IEEE 802.11p is a popular standard for dedicated short-range communications (DSRC) (Bazzi et al. 2017; Ligo et al. 2018). It is mainly designed for vehicular communications. The US Federal Communications Commission (FCC) allocates dedicated 75 MHz bandwidth at 5.9 GHz for DSRC. In addition, this bandwidth is divided into seven channels that can be used by safety and nonsafety services.

mmWave: The IEEE 802.11ad working group introduced the operation of multigigabit wireless data transfers over the unlicensed 60 GHz band (i.e., the mmWave band) (Yilmaz et al. 2016). The 60 GHz bands provide 7 GHz bandwidth that can provide up to 6.76 Gbps which can support IoT applications where a very high data rate is required. The PHY layer of this standard has four transmission modes, namely, (i) control mode for beaconing and initial network setup, (ii) single carrier (SC) mode with the data rate up to 4.62 Gbps, (iii) orthogonal frequency division multiplexing (OFDM) mode with the highest data rate of 6.75 Gbps, and (iv) low-power SC mode to support to resource-limited devices.

LoRa

LoRa (Long Range) is one of the emerging wide area wireless technologies (Raza et al. 2017; Navarro-Ortiz et al. 2018) which was initially developed by Semtech

(<http://www.semtech.com/wireless-rf/internet-of-things/what-is-lora/>) and later was promoted by the LoRa Alliance (www.lora-alliance.org/technology). Optimized for low power consumption, LoRa utilizes chirp spread spectrum (CSS) modulation technology to support millions of devices and long-range communication of small data packets. The end IoT devices communicate with gateways through a single hop LoRa wide area network and all gateways are connected to a network server by backhaul connection. The main functions of the network server include filtering duplicate packets from gateways, ensuring security, sending acknowledgments to the gateways, and transmitting the packets to their destinations.

Long Term Evolution (LTE)

LTE and its revision LTE-Advanced (LTE-A) are wide area cellular communications standard developed by third Generation Partnership Project (3GPP) for high-performance communications involving human-operated mobile or similar devices. According to a recent Ericsson Mobility Report (www.ericsson.com/en/mobility-report), in 2017, LTE systems provided communication services to over 2.1 billion of users across the globe. The widespread use of LTE is mainly due to its global standard infrastructure and more flexible radio resource management techniques than other previous cellular technologies. However, the evolution of LTE system promises to meet requirements in large-scale IoT deployments by addressing IoT use cases. Already 3GPP has launched initiatives to modify and optimize the LTE standard to adapt it to IoT applications. These initiatives include LTE for machine type communications (LTE-M) and narrowband IoT (NB-IoT).

LTE-M: LTE-M is a simplified term of LTE-MTC which provides wireless access to IoT applications by reusing LTE installed base stations (Hoymann et al. 2016; Lauridsen et al. 2017). Here, MTC refers to machine type communications where IoT devices are allowed to communicate with each other without human intervention. Today, MTC is an essential part of IoT as it supports devices that access

and communicate with a gateway or access point in various IoT scenarios. Moreover, LTE-M offers device to device (D2D) communications which allow devices in close proximity to communicate directly without going through a base station. This direct connectivity can significantly increase network spectral efficiency, reduce the transmission delay, offload traffic, and avoid congestion in the core network.

NB-IoT: Another initiative by 3GPP called NB-IoT aims to develop a new radio access network to support IoT applications with low data rate (Miao et al. 2018; Xu et al. 2018). Although NB-IoT operates in the narrow band (a new air interface derived from the legacy LTE), NB-IoT inherits the basic features of the LTE standard. However, many features of LTE such as handover mechanism, carrier aggregation, and dual connectivity have been removed to minimize device costs and power consumption.

Table 2 presents a summary of the main characteristics of the wireless technologies we have discussed above.

Pros and Cons of Candidates and Suitable IoT Applications

This section identifies and evaluates viable wireless technologies that can provide efficiently for the various IoT applications shown in Table 1.

To support short-range communication, BLE is promising for many IoT applications mainly due to its low power consumption. Moreover, we foresee an increasing number of smartphones as well as consumer devices equipped with BLE interfaces in the near future. In fact, the BLE interface is already available in most smartphones, and consequently, BLE will have a larger market than ZigBee. The Bluetooth SIG predicts (www.bluetooth.com/pages/mobile-telephony-market.aspx) that by 2018 more than 90% of Bluetooth-enabled smartphones will include BLE. As a result, BLE will become the most common communication medium in IoT scenarios where user to device interactions are required such as in smart home and smart healthcare applications. Regarding interference

issue with 2.4 GHz WiFi, BLE can provide good performance as it uses an adaptive frequency hopping scheme.

The mmWave is well suited for IoT applications, which require high network bandwidth such as high definition video sharing within vehicular communication scenarios. But the main shortcomings of mmWave are its high power consumption, severe propagation loss, and signal attenuation which result in a short-range coverage. However, as the wavelength of 60 GHz is at the millimeter level, it is possible to apply beamforming technique in mmWave by packing a large number of antennas into a small space. Beamforming is a signal processing technique that concentrates power in one direction in order to achieve one directional signal transmission or reception by a smart antenna array. Although mmWave covers about 10 m in omnidirectional broadcast mode, by utilizing beamforming, mmWave allows transmission ranges up to 130 m with data rates up to 385 Mbps and 2 Gbps for a range of 79 m. Moreover, the directional signal can track both moving and stationary objects over a 100 m distance. As a result, beamforming utilized by mmWave can be useful for an IoT application such as smart transportation.

In many IoT applications, an access point (AP) or gateway has to support many devices that periodically send short data packets over a long distance. In fact, LPW and WhiteFi are designed to support such IoT scenarios. Moreover, increased sleep time capability allows LPW-equipped device to sleep for a very long period of time, wake up infrequently to send or receive the data packet, and go back to sleep. Both WiFi and WhiteFi have favorable propagation characteristics, reduced path loss, and better wall-penetration characteristics which make key enabling technologies for many of IoT applications.

DSRC is designed particularly for vehicular communications which supports a large number of vehicles often connected to an AP. The US Department of Transportation recommends using IEEE 802.11p-based DSRC

Emerging Wireless Technologies for Internet of Things Applications: Opportunities and Challenges, Table 2
Summary of candidate wireless technologies for IoT applications

Technology	BLE	LPW	mmWave	DSRC	WhiteFi	LoRa	LTE-M	NB-IoT
Standardization body	Bluetooth SIG	IEEE	IEEE	IEEE	IEEE	LoRa Alliance	3GPP	3GPP
Frequency band	2.4 GHz	Sub-1 GHz	57–64 GHz	5.86–5.92 GHz	TVWS	Sub-1 GHz	7–900 MHz (licensed)	7–900 MHz (licensed)

on light-duty vehicles (http://www.its.dot.gov/factsheets/dsrc_factsheet.htm). But the DSRC technology has limited bandwidth and it can only support a maximum data rate of up to 27 Mb/s.

LoRa, LTE-M, and NB-IoT are three potential long-distance transmission technologies. We note that unlicensed LoRa offers benefits such as power consumption, coverage area, and cost, whereas licensed LTE-M and NB-IoT have advantages in terms of QoS, latency, security, and reliability. LoRa can manage interference and multipath fading well because it uses CSS modulation. LoRa is an asynchronous protocol, whereas LTE-M and NB-IoT are time slotted synchronous protocols. Consequently, LoRa cannot provide the same QoS as LTE-M and NB-IoT do. But this QoS benefit is at the expense of increased cost because the licensed band spectrum is generally a more expensive resource. Hence, the applications that require QoS should choose LTE-M or NB-IoT, whereas applications that do not require high QoS may choose LoRa.

The operating bandwidth of NB-IoT (200 kHz) is narrower than LTE-M (1.08 MHz). The main reason for choosing a narrow band is because LTE-M utilizes the licensed spectrum which is already highly used for human-type traffic and to support a large number of devices.

However, a single NB-IoT carrier can support more than 100,000 low data rate devices, and it can increase up to millions of connections if several carriers are used where the LTE-M fails to support.

Figure 2 summarizes the wireless technologies based on the different IoT communication requirements. Table 3 shows a summary of the benefits, limitations of wireless technologies, and their suitability for possible IoT applications.

Case Studies

In this section, we present several case studies that have been reported in the recent literature. We discuss these various previous case studies to present the types of wireless technologies that are being used by different IoT applications.

In Lin et al. (2015), the authors demonstrate an experiment on BLE in smart vehicle IoT application. In this experiment, the authors used Texas Instruments' BLE system-on-chip solution CC2540 (<http://www.ti.com/product/CC2540>) which contains a BLE node and a USB dongle. The BLE node is powered by a CR2032 230 mAh lithium battery. The application layer and a universal asynchronous receiver/transmitter (UART) interface are implemented on an

Emerging Wireless Technologies for Internet of Things Applications: Opportunities and Challenges, Table 3
Potential wireless technologies for IoT applications

Technologies	Benefits	Limitations	Possible IoT applications
BLE	Point to point, broadcast and mesh support; power saving mechanism is available; large market; widespread adoption in smartphones and consumer electronic devices; support up to 65,000 cell nodes	Crowded spectrum; low data rate; short range; limited bandwidth	Smart Home, Smart Meter, Smart Healthcare, Smart Vehicles
LPW	Low energy consumption by utilizing power saving mechanisms; backhaul connections are supported, adopting a novel hierarchical method that supports up to 8191 devices associated with an AP	Crowded spectrum; attenuation problem	Smart Building, Smart Grid, Smart Industry, Smart Security
mmWave	Worldwide availability, high data rate; high channel bandwidth; mobility support up to 350 km/h	Short range, does not penetrate concrete walls	Smart Vehicles, Smart Transportation, Smart Security, Smart Industry
DSRC	Dedicated but unlicensed only for vehicular communications; mobility support up to 190 km/h	Moderate data rate	Smart Transportation, Smart Vehicles
WhiteFi	Good propagation characteristics; backhaul connections supported; long range	Vulnerable to wireless security attacks	Smart Grid, Smart City
LoRa	Good propagation characteristics; the number of supported devices is around 10^4 per gateway; already deployed and tested; broad coverage area	Lack of expertise to design network	Smart City
LTE-M and NB-IoT	Good propagation characteristics; backhaul connections are unsupported; the number of LTE-M and NB-IoT devices that can be support is around one million and 200,000, respectively; QoS guaranteed; mobility support up to 350 km/h	High cost due to infrastructure and licensed band; depends on current LTE infrastructure; competing against unlicensed LoRa	Smart City, Smart Transportation

electronic control unit (ECU) inside the vehicle. The USB dongle is connected to the ECU through the UART and its adaptation layer serves as the interface between the host and the ECU. Finally, the average current consumptions during connection event and sleep state are obtained 10.655 and 0.9 mA, respectively. Moreover, if the message is transmitted every 2 s, the average current consumption computed from a calculation is 0.013 mA. Finally, the authors estimated that the 230 mAh coin battery life could last around 2 years.

The authors in Adame et al. (2014) present the key features of the IEEE 802.11ah LPW amendment which relates to the decreasing of energy consumption in the MAC layer. They conducted a performance evaluation using MATLAB. They used a one-hop fully connected network and the IoT devices were uniformly distributed within the AP coverage for IoT application scenarios such as agriculture, animal monitoring, smart metering, and industrial automation. The aforementioned scenarios used 3500, 250, 15, and 500 devices, respectively; each device sends data every 120, 60, 50, and 180 s, respectively. In addition, for these scenarios, the energy consumptions obtained were 112, 99, 18, and 25 nJ/bit, whereas, the battery lifetimes were estimated to be 2, 4, 6, and 5 years, respectively. Here to calculate the battery lifetime, the authors used a 2200 mAh lithium battery.

Linghe Kong et al. (2017) explore the capability of mmWave communications for intelligent transportation applications by proposing a novel cloud integrated design of a mmWave system. Moreover, they developed a prototype in a 100 m × 15 m area with three road segments on 30–100 vehicles. Here, all road-side infrastructures and vehicles are equipped with mmWave communications to utilize both vehicle to vehicle (V2V) and vehicle to Internet (V2I) communication support. V2V supports the real-time multimedia data sharing among vehicles, whereas V2I utilizes the roadside infrastructure and cloud computing in order to respond to recognized objects and signs. Finally, they observed that the mmWave demonstrates better channel utilization than DSRC. Figure 3 shows the performance

results of their prototype. In this case, as the number of wireless links used by vehicles increases, both DSRC and mmWave yield a steady linear increase only up to a certain point. This is mainly due to radios in each other's interference coverage area cannot build new wireless links.

Centenaro et al. (2016) described an experiment of IoT networks (smart city) based on LoRa. This experiment was conducted in the Italian city of Padova which has a lot of buildings and shopping malls. In such a harsh propagation condition, the experimental test confirmed that LoRa can support satisfactory long range coverage up to 2 km. Finally, the authors estimated that 30 LoRa gateways would be enough to cover the entire city of Padova which is about 100 square km. Another LoRa empirical test-bed was built (Augustin et al. 2016) and a performance evaluation was carried out in a suburban area of Paris with low-rise residential buildings. About 10,000 data packets were transmitted from end devices to the LoRa gateway and the signal strength of the received packets was measured. From this field trial, the results obtained showed that LoRa was able to cover a gateway around 3 km radius in a suburban area.

Open Issues

This section presents some open challenges and identifies future research opportunities.

In various IoT scenarios, applications need different QoS requirements in terms of data rate, latency, and reliability. To fulfill QoS requirements becomes challenging particularly in unlicensed bands when there are a large number of connections. Hence, future research needs to focus on the development of QoS-aware protocols that can efficiently support QoS requirements while increasing the coverage area and the number of connections. As we have discussed previously, many IoT applications are delay-sensitive. In the future, new techniques such as D2D communications and local cloud or edge computing have to be carefully integrated to reduce end-to-end communication delays. Moreover, some applications (for example smart

Emerging Wireless Technologies for Internet of Things Applications: Opportunities and Challenges, Fig. 3

The result of the number of vehicles vs the average number effective wireless links (Kong et al. 2017)

E

health) are not only latency sensitive but also data packet loss sensitive. On one hand, in these applications, lost or corrupt data packets for the unreliable network will have serious consequences. On the other hand, some IoT devices are too resource limited to retransmit unacknowledged data. Hence, the reliability issues will have to be defined also.

Future IoT wireless networks will face various security threats such as jamming attack, eavesdropping attack, malicious gateway, or AP during communications. Hence, wireless security techniques need to be improved by considering large-scale connectivity in the future IoT ecosystem. Moreover, security solutions incur additional energy consumption which is a concern in IoT scenarios given that many devices are resource-constrained. Consequently, ensuring security while minimizing the energy consumption needs to be further investigated. We need novel security solutions that can adequately balance the trade-off between security and energy consumption.

We have already mentioned earlier that many IoT devices are battery-powered with very limited processing capability and some of the devices will have to depend on energy harvesting sources. However, to enable large-scale IoT deployments, very low power technologies are required. Although some such technologies have been developed, they are still at an early stage

and still need to be fully tested, evaluated to analyze their suitability. Moreover, emerging low power listening techniques need to be explored which can minimize the power consumption by idle listening.

The amount of generated data in IoT will continue to grow further stressing our communication infrastructures. To manage this exponential growth of IoT data efficiently, we need to develop new networking approaches that can handle a high volume of network traffic efficiently.

Finally, as the licensed spectrum is not free and users need to pay for using it, new policies, economic and pricing models compatible with emerging IoT markets need to be developed when deploying licensed technologies into IoT applications.

Conclusion

The deployment of IoT applications is accelerating with the help of wireless technologies. In this work, we have presented the most promising and viable wireless solutions suitable for IoT applications. We have analyzed the communication requirements of IoT and identified appropriate wireless technologies that can meet those requirements. Several open issues remain to be addressed which we have discussed. We hope this work will be helpful in guiding design-

ers and researchers on the wireless technology choices available for massive IoT deployments. A discussion of power saving mechanisms, communication security, and more deployment case studies will be undertaken as part of our future works.

[Encrypted search](#); [Privacy-preserving healthcare service](#)

Definition

Encrypted search over medical data is a set of versatile techniques that allow the data storage server to directly search over different types of encrypted medical data without decryption. Only the data owner and authorized clients with the decryption key can access the data and search results in cleartext.

Historical Background

In the modern age, medical data is digitalized to improve quality of care, promote evidence-based medicine, and facilitate trace of diagnosis and treatment. Despite the benefits expected from it, the data privacy and security issue is still one of the greatest obstacles that hinders the development of digital healthcare systems and services. As surveyed by Fernández-Alemán et al. (2013), over millions of personal medical data records are leaked each year. Because medical data contains personal and private information of patients, the disclosure of such sensitive data raises serious concerns across the entire society. To mitigate the issue, laws and regulations are formulated. For example, the recent HITECH US Health Care Law requires the responsible party to report breaches involving more than 500 patients (Blumenthal 2010). Unfortunately, those policies hardly prevent from massive data breach incidents nowadays. Unauthorized disclosure of medical data can be caused by both unintentional behavior (e.g., software vulnerability or misconfiguration) and intentional behavior (e.g., trading personal information for profits). Also, the threats can be originated from both external and internal entities.

Conventional approaches of protecting medical data are classified into three different techniques, access control, anonymization, and transparent encryption. For a given data item, access control policies specify the privilege scope of the data access at the user or group levels. However, this approach cannot guarantee data confidentiality. No matter how strict access control policies are, data is stored in cleartext. The administrator of the data storage can view the data without any limits. Besides, once a hacker compromises the data storage, all data records are exposed. Another approach is anonymization; patients' identity information is extracted from their medical records before publishing. However, the linkability between patient identities and sanitized data records is possible to be recovered through some disambiguation process if some background or side information is exploitable. To guarantee

strong protection for medical data, encryption is a common practice. Off-the-shelf database systems offer transparent encryption; data is encrypted by the data storage server once the data is written to the database. Unfortunately, this approach relies on the server (not the data owners) to encrypt data for client transparency. Therefore, threats of stealing data still exist as long as the hacker could control the server and obtain the encryption key.

One candidate approach of ensuring confidentiality of medical data is to adopt client-side encryption. Medical data records are encrypted at the client before storing to the database at the server. Without the client's private encryption key, the server always sees the ciphertexts, and the attacker who compromises the server has no access to the data in cleartext throughout its life cycle. But the data storage server now loses the capability of searching and processing medical data and can no longer provide useful healthcare services. How to preserve the utilization of medical data in the encrypted domain becomes an emerging question. As search is a ubiquitous function of data management and analytics, enabling the server to search over encrypted medical data without decryption is demanding for secure and efficient digital health applications. Although there exist generic cryptographic primitives (Shan et al. 2018) that support arbitrary computation such as fully homomorphic encryption and secure multi-party computation, those primitives are too expensive to handle large volumes of encrypted medical data in the real world. Here, we focus on symmetric key-based primitives and introduce three practical applications for searching different types of medical data in different contexts.

Key Applications

Searching Encrypted Textual Medical Records

In digital healthcare, paper-based health records are transformed into electronic health records (EHRs) and stored in the database system for easy management. As mentioned, client-side

encryption is desired for strong protection of data confidentiality. But how to preserve the query functionality of the database over encrypted medical data records becomes an obstacle. After medical data records are inserted to the database, doctors may later search patients' data for diagnosis, prediction, medicine recommendation, and decision-making. Common query functions include quality checks, range queries, joins, and aggregation. Apart from functionality, it is also desired that the adopted techniques should be integrated into the off-the-shelf database management system in a minimally intrusive manner.

To realize the above goals, one may adopt CryptDB, an encrypted relational database management system (RDBMS) designed by Popa et al. (2011). This system implements a set of practical cryptographic primitives to support different SQL query functions, respectively. In particular, CryptDB uses deterministic encryption (DET) for equality check, because DET ciphertexts preserve the quality of the underlying plaintexts. It also uses order-preserving encryption (OPE) for range queries, because OPE ciphertexts preserve the order relations of the underlying numeric data values. On the other hand, proxy re-encryption is used to support the above queries over multiple data attributes encrypted via different keys. The server will transform the ciphertext encrypted from one key to another before equality check and range match. Moreover, additive homomorphic encryption is adopted to support aggregation on encrypted data values.

To improve security and efficiency, CryptDB implements a technique called onion encryption. The values in each data record are encrypted in a layered manner. Based on the related query functions on a data value, it is first encrypted via property-preserving encryption schemes like DET or OPE and then encrypted via randomized encryption. As a result, the server can save some space cost of storing the same data value yet encrypted via different encryption schemes. In addition, if the hacker could only obtain the snapshot of the database, all data values are still strongly protected with semantic security. No

partial information such as equality and order relations is revealed.

Searching Encrypted Medical Images

Digital medical data is not only in the textual format but can also be depicted as images such as magnetic resonance imaging (MRI). In this application context, exact-match queries rarely exist, while similarity queries are more desired. Finding similar medical images in some database with respect to a given query image of a patient is crucial for doctors to conduct disease diagnosis and further decision of treatment. In practice, images are represented as high-dimensional vectors (features), and the similarity of images can normally be quantified by a certain distance between those high-dimensional vectors. To support similarity search over encrypted medical images, one naive approach is to employ secure protocols supporting distance computation on ciphertexts. However, computing pairwise distances between the query image and each image in the database is not scalable even in the plaintext system.

To solve this problem in a secure and efficient manner, Yuan et al. (2015) propose a protocol that systematically integrates the advances in similarity search and encrypted search. Their idea starts from locality-sensitive hashing (LSH) (Andoni and Indyk 2008), an approximate and randomized algorithm for fast similarity search. LSH functions hash high-dimensional vectors in a way that the close ones collide with much higher probability than the distant ones. As a result, the problem of similarity search is transformed to exact matching of LSH hash values derived from image vectors. To enable such matching in the encrypted domain, they further adopt searchable symmetric encryption (SSE) (Curtmola et al. 2011), a practical primitive supporting keyword search in sublinear time complexity. Their methodology is to treat LSH hash values as keywords.

The above direct combination is not practically deployable because of the performance bottleneck raised by the imbalance of LSH. Each

vector needs to be hashed by several LSH functions for accuracy assurance, and one or several query LSH hash values might match a large number of candidate image vectors, leading to high I/O and long latency. To address this issue, they devise a tailored encrypted index from the scratch. This design leverages high-performance hash-based structures, including multiple-choice hashing, cuckoo hashing, and open addressing, and incorporates them into the security framework of SSE. Specifically, they apply pseudo-random functions to protect sensitive LSH hash values, use symmetric encryption to encrypt the index content, and implement the above hash-based optimizations in a random fashion. The resulting encrypted index achieves a high load factor, constant search time, controllable trade-off of accuracy, and privacy preservation for medical image vectors.

Searching Encrypted Streaming Medical Data Signals

Another common type of medical data is generated from medical devices and sensors, because healthcare applications demand routine monitoring to capture a deluge of high-quality information of patients' pulses and motions. For example, a transceiver continuously monitors the physiological signal of a patient, and its sensor can produce up to 31 GB data every day (Yuan et al. 2016). To manage a large scale of medical data signals, cloud-based services are currently used which can link millions of sensors and process data acquired from them. Again, exposing them in a cloud environment may violate regulations of data privacy and cause unauthorized data access. Accordingly, client-side encryption has to be enforced before medical data signals are inserted to the cloud server. Note that those signals are normally generated from sensors in a streaming fashion. Then how to search and process those encrypted and streaming medical data signals becomes even more challenging.

To tackle this challenge, Yuan et al. (2016) propose a privacy-assured framework that can

fast index encrypted medical data signals generated at a high rate. Their first key observation is that unified data sampling and compression techniques like compressive sensing (Candès and Wakin 2008) are being increasingly integrated into hardware sensors to accelerate the acquisition of medical data and reduce the computation and energy consumption during data acquisition. In the meanwhile, one salient feature of compressive sensing is that the Euclidean norm of raw data signals is still preserved in the measurement space of compressed samples. Therefore, doctors are still able to utilize and search over those compressed medical data samples for high-value results, e.g., similar samples. Under this context, the proposed framework introduces a gateway server operated by the trustworthy data owner. It continuously collects data samples from sensing devices via some certain compressive sensing algorithm. But how to encrypt and fast index those samples before sending to the cloud for later use is nontrivial.

This framework resorts to a high-performance encrypted index for similarity search proposed in Yuan et al. (2015). To achieve a high indexing throughput for streaming medical data signals, a new algorithm is designed to construct the above encrypted index with multi-threading support, i.e., enabling parallel insertion while guaranteeing thread safety. In particular, an efficient locking technique called optimistic locking is integrated to the security framework of SSE and the advanced LSH indexing techniques. The proposed concurrent indexing algorithm achieves the optimal number of locks for write operations and avoids intensive use of locks for read operations when seeking multiple index buckets in each insertion. Based on this, this framework includes a secure bulk update mechanism to index continuously generated medical data samples in a batch manner.

Future Directions

To better support privacy-preserving query services for medical data, there are several

challenges yet to be addressed. From the perspective of service scalability, existing approaches and systems focus on the centralized setting where one single server handles and searches all encrypted medical data records. But in practice, a massive amount of medical data is distributed in a cluster of servers. How to enable distributed computing in this domain is demanding. One potential approach is to resort to the distributed framework of the distributed data store and enable parallel query processing in the encrypted domain (Liu et al. 2017). From the perspective of enriching functionality, supporting more advanced computation tasks over encrypted medical data can improve service of quality in digital healthcare while preserving the patient privacy. Recent studies investigate medical image reconstruction (Wang et al. 2013; Shan et al. 2018) and similarity join queries (Yuan et al. 2017), while complicated data analytic functions such as outlier detection in time-series medical data signals and classification over encrypted medical images also need to be explored. From the perspective of security, recent attacks against encrypted search (Naveed et al. 2015; Cash et al. 2015) demonstrate that real-world attackers can still compromise the privacy of the encrypted database if they have access to some background knowledge of the original dataset. The side information captured from the query process can be exploitable with the background knowledge to efficiently recover the plaintext dataset and queries. How to address those new threats efficiently with theoretical guarantee is a challenging and emerging problem in the near future. Otherwise, questions might be raised on whether those primitives and systems supporting encrypted search can securely be adopted for sensitive medical data.

Definition

Energy efficiency of cellular networks aims to improve energy efficiency and resource efficiency of the cellular networks without compromising the quality of services for the users.

Historical Background

During the last decade, there has been tremendous growth in cellular networks' market. Such unprecedented growth in cellular industry has pushed the limits of energy consumption in wireless networks (Hasan et al. 2011). The rising energy costs and carbon footprint of operating cellular networks have led to an emerging trend of addressing energy efficiency among the network operators and regulatory bodies such as the 3rd Generation Partnership Project (3GPP) (3GPP 2010) and the International Telecommunication Union (ITU) (ITU 2010). In this context, the European Commission has recently started new projects within its Seventh Framework Programme to address the energy efficiency of mobile communication systems, i.e., "Energy

Aware Radio and NeTwork TeCHnologies (EARTH)" (Energy Aware Radio and Network Technologies [Earth](#)), "Towards Real Energy-efficient Network Design (TREND)" (Towards Real Energy-Efficient Network Design [Trend](#)) and "Cognitive Radio and Cooperative strategies for Power saving in multi-standard wireless devices (C2POWER)" (Cognitive Radio and Cooperative Strategies for Power Saving in Multistandard Wireless Devices [c2power](#)). In the future fifth-generation (5G) wireless networks, costs, and energy consumption are expected to, ideally, decrease, but at least they should not increase on a per-link basis (Andrews et al. 2014).

Foundations

Proportions of Energy Consumption

The power consumption of a typical wireless network is mainly for base station (BS), mobile switching, core transmission, data center, retail, etc., in which over 50% is consumed by BSs. In Humar et al. (2011), embodied energy – consumed by all processes associated with the production of equipment – is proposed and is found that embodied energy accounts for a significant proportion of total energy consumption and cannot be neglected. The power consumption by a BS (aka eNodeB in the fourth generation and beyond wireless networks) is illustrated in Fig. 1. Multiple transceivers constitute a BS, and each transceiver consists of a power amplifier, a radio-frequency small-signal transceiver module, a baseband unit (BBU), a DC-DC power supply, an active cooling system, and an AC-DC unit (Ge et al. 2017).

Energy Efficiency Metrics

A classical and widely used metric to evaluate the energy efficiency of telecommunication networks is Bit-per-Joule (Wu et al. 2015). The reciprocal of Bit-per-Joule measurement, namely, energy consumption per delivered information bit, is referred as energy consumption ratio (ECR). A close variant to the Bit-per-Joule metric is Bit-per-Joule-Hz. Instead of system throughput (bits/s), Bit-per-Joule-Hz uses spectral efficiency

Energy Efficiency of Cellular Networks, Fig. 1 The power consumption of a BS (aka eNodeB in the fourth generation and beyond wireless networks)

(bits/s/Hz) as the performance measurement, which is equal to the ratio of spectral efficiency over the total power consumption. In Table 1, a summary of energy efficiency metrics is listed, and several references are recommended.

Methods to Improving Energy Efficiency

Various distinctive approaches can be utilized to reduce energy consumption in a mobile cellular network. Approaches in previous research can be broadly classified into the following five categories.

(1) Improving energy efficiency of hardware components: The energy of cellular networks is mainly consumed by two types of components, i.e., BBU and radio-frequency unit (RFU). Therefore, the way to improve the energy efficiency of hardware components can be divided into two categories. One category is to improve the energy efficiency of BBUs, such as applying latest semiconductor technology to BBUs' chip and designing low overhead algorithm for

BBUs' processing. Another category is to improve the energy efficiency of RFUs, such as applying higher efficiency of the power amplifier to RFUs and changing the connection structure between radio-frequency links and antennas (Zi et al. 2016).

- (2) Turning off components selectively: In practice, the BS density, cell size, and cell capacity are designed to satisfy the requirement of peak traffic, and hence, some BSs are idle at low traffic, which leads to significant energy waste. Selectively turning off components of lightly loaded BSs is proposed to save energy. With aiming at optimization on energy saving only or another energy-related performance trade-offs, several BS switch-off strategies have been proposed from different design perspectives, such as random, distance-aware, load-aware, and auction-based strategies (Jia et al. 2016).
- (3) Optimizing energy efficiency of the radio transmission process: With the rising energy costs and carbon footprint of the cellular

Energy Efficiency of Cellular Networks, Table 1
Energy Efficiency Metrics

Metric	Description	References
Bit-per-Joule	Ratio of effective system capacity over energy consumption	(Ge et al. 2014a, 2015, 2016, 2017)
Bit-per-Joule-Hz	Ratio of effective system capacity over energy consumption in unit bandwidth	(He et al. 2012 Ge et al. 2014b)
Joule-per-Bit	Ratio of energy consumption over effective system capacity	(Badic et al. 2009)
Bit-per-Joule-km ²	Ratio of effective system capacity over energy consumption in a unit area	(Yang et al. 2017)

- networks, optimizing the energy efficiency of the radio transmission process is a critical problem for the future communication systems. Since the power usage of the BS is over 50% of the cellular network power consumption, the optimization of the energy efficiency of the BS is the primary issue to solve. Multiple transceivers constitute a BS, and a transceiver consists of a power amplifier, a radio-frequency small-signal transceiver module, a baseband engine, a DC-DC power supply, an active cooling system, and an AC-DC unit. Furthermore, the power amplifier, the radio frequency, and the baseband engine cost most of the power, so to optimize the energy efficiency of the radio transmission process, the above three mentioned items should be focused (Ge et al. 2017).
- (4) Planning and deploying BSs: Deploying small cells, including micro, pico, and femto cells, in the cellular network. These smaller cells serve small areas with dense traffic with low power-consuming cellular BSs, which are affordable for user deployment and usually support the plug-and-play feature. In contrast to conventional homogeneous macro cell deployment, such heterogeneous deployment reduces energy consumption in the network by shortening the propagation distance between nodes in the network and utilizing higher-frequency bands to support higher data rates (Wu et al. 2015).
- (5) Network resource allocation: Roughly speaking there are two types of resource allocation methods; one is uniform resource

allocation, and the other is nonuniform resource allocation. Uniform resource allocation technologies mainly focus on the fairness between network users to ensure that each user can achieve an acceptable quality of service, while nonuniform resource allocation technologies mainly aim at the enhancement of network performance like sum capacity, throughput, and energy efficiency. Although network resource allocation is quite an old topic, there are still a lot of unsolved problems when fairness and performance are both considered, and issues become even more complicated with energy efficiency constraints.

Key Applications

Information and communication technology (ICT) already represents around 2% of total carbon emissions (of which mobile networks represent about 0.2%), and this is expected to increase every year. In addition to the environmental aspects, energy costs also represent a significant portion of network operators’ overall expenditures (OPEX). While the BSs connected to electrical grid may cost approximately 3000\$ per year to operate, the off-grid BSs in remote areas generally run on diesel power generators and may cost ten times more. To address the challenge of increasing power efficiency in future wireless networks and thereby to maintain profitability, it is crucial to consider various paradigm-shifting technologies,

such as energy efficient wireless architectures and protocols, efficient BS redesign, smart grids, opportunistic network access or cognitive radio, cooperative relaying, and heterogeneous network deployment based on smaller cells.

Energy Harvesting Cognitive Radio Sensor Networks

Deyu Zhang

School of Software at Central South University,
Changsha, China

Definitions

Energy harvesting cognitive radio sensor networks operate over idle licensed spectrum using harvested energy. By harvesting energy from the ambient energy sources, such as solar and wind, sensors can achieve sustainable operation without human intervention. In addition, cognitive radio enables sensors to exploit spectrum holes without causing interference to primary users.

Historical Background

Traditional sensor networks consist of miniaturized and low-end sensors powered by batteries with limited capacity. To guarantee the long-term operation, an operator needs to manually replace the depleted battery, which results in considerable maintenance cost. In addition, sensors are networked through the free-of-charge unlicensed spectrum, i.e., the industrial, scientific, and medical (ISM) spectrum, which is becoming more and more congested due to the flourish of Wi-Fi networks. As the miniaturization of energy harvesters and software defined radios, both the academia and industry come to realize that energy harvesting (EH) and cognitive radio (CR) techniques provide promising solution for the resource constraint issue of traditional sensors. The solar panel is first incorporated into sensors to achieve long-lived operation in the early twenty-first century (Lin et al. 2005). After that, numerous researches of EH sensor networks emerge with topics ranging from power management (Kansal et al. 2007), to modeling of EH process (Ku et al. 2015),

to residual energy-balanced cooperative transmission (Zhang et al. 2016b). To liberate sensors from interferences with other unlicensed networks, Akan et al. (2009) propose cognitive radio sensor networks to enable the opportunistic access of licensed spectrum. Park and Hong (2013) and Park et al. (2013) firstly combine EH and CR techniques in wireless networks. The works investigate the joint schedule of spectrum sensing and access powered by harvested energy. The milestones of EHCRSN appeared in 2016–2017, i.e., Ren et al. (2016); Zhang et al. (2016a, 2017). Ren et al. (2016) optimizes the spectrum access and energy allocation to optimize the network. Without assuming any prior information of the EH process and activities of primary users (PUs), Zhang et al. (2016a) develop an aggregate network utility optimization framework for the design of an online energy and spectrum management based on Lyapunov optimization. Zhang et al. (2017) employ EH-powered spectrum sensors to detect the licensed spectrum to alleviate the spectrum scarcity problem in sensor networks.

Foundations

A typical EHCRSN consists of a sink and numerous sensors with EH and CR modules. The EHCRSN coexists with a primary network which has the privilege to access the licensed spectrum. The sensors use harvested energy to sense data from the AoI and then transmit the sensed data to the sink through the idle licensed spectrum, as shown by green links in Fig. 1. To avoid the interference to PUs, the spectrum detection is mandatory, which can be realized by either a third party system (TPS) or the sensors themselves. Other than sensed data, the sensors may exchange auxiliary information with each other and the sink for spectrum handoff, sensing rate control, routing, etc.

Figure 1 describes a typical EHCR sensor, which consists of five modules: the EH module, rechargeable battery, data sensing/processing module, data buffer, and CR transceiver. The

Deyu Zhang

Energy Harvesting Cognitive Radio Sensor Networks, Fig. 1 Node structure of an EHCR sensor

EH module harvests energy from ambient energy sources and store the energy in the rechargeable battery. The stored energy can be used by the data sensing/processing module which is responsible to collect information from the AoI, and the CR transceiver which detects the licensed spectrum receives and transmits data over the spectrum. The received and sensed data are stored in the data buffer. The ambient energy sources to harvest from determine the type of the EH module. For example, the energy in sunlight can be harvested by solar panel, and the energy in changes of ambient conditions, such as pressure, temperature, and acceleration, can be transformed into electric energy by piezoelectric transducers. To store harvested energy and prevent the impacts of batteries memory effect, the super capacity or lithium-ion battery are considered as competitive candidates for rechargeable battery in the EHCR sensors.

Considering the limitation on the manufacture cost of sensors, the low-cost CR transceivers are desired, which can cover the licensed spectrum of interest, i.e., the spectrum that is accessible to EHCR sensors. Since the price of the CR transceivers tends to increase with the width of the tunable frequency range, it is important to choose the CR transceiver according to the accessed licensed spectrum.

Key Applications

With EH and CR capabilities, EHCRSNs can perform monitoring and surveillance tasks sustainably while overlapping with other unlicensed networks, such as Wi-Fi hotspots and Bluetooth. Therefore, the applicability of EHCRSNs is significantly improved in various real-life scenarios such as smart city, indoor surveillance and localization, and electronic health.

Future Directions

From the evolution of wireless sensor networks, it appears that the future needs will come from the modeling of EH process and PU activities, the joint spectrum sensing and access schemes using harvested energy, as well as the routing in multi-hop EHCRSNs. In the following are some future directions:

- *The Modeling of EH process and PU activities based on real data trace.* This issue remains open mainly due to the lack of comprehensive historical data records in EH process and licensed spectrum usage. In the coming era of Internet of Things, more data records

of the two processes can be complemented by the widely deployed devices with sensing capability, e.g., smartphones. Based on the records, the operator can use the data mining and machine learning techniques to extract the statistical information of EH process and PU activities.

- *Joint Spectrum Detection and Access.* For EHCR sensors, both the exploration and exploitation of licensed spectrum consume energy which makes the coupling of energy and spectrum allocation more complex. The tradeoff exists between the accurate information on PU activity and immediate spectrum access.
- *Resource Allocation in Multi-hop EHCRSNs.* Some sensor networks may consist of thousands of nodes which transmit data to the sink through multi-hop relaying. Considering the signaling overhead of centralized algorithms, distributed algorithms are desired to improve the scalability of EHCRSNs. To utilize the benefits brought by EH and CR capabilities, sensors need to frequently adjust power control, change next-hop relay, and vacate operating channels.

Energy Harvesting Sensor Node Scheduling in Wireless Sensor Networks

Liang Huang

Definitions

In wireless sensor networks (WSNs), an *energy harvesting sensor node* harvests ambient energy from the environment and converts it into electrical energy to support continuous WSN oper-

ations without energy depletion. To overcome the dynamic feature of energy harvesting, *energy harvesting sensor node scheduling* jointly regulates data transmission and energy management to achieve reliable and efficient operations in WSNs.

Historical Background

WSNs have been widely deployed in the past decades for various applications, for example, environmental monitoring (Adu-Manu et al. 2018), animal tracking (Szewczyk et al 2004), and smart cities (Bakakeu et al. 2017). They consist of a number of low-cost and battery-operated sensor nodes that transfer sensed data over the air. An important performance metric of WSNs is the lifetime constrained by limited batteries. Over the years, different energy-efficient sensing and communication protocols (Khajuria and Gupta 2015) have been developed to minimize the energy consumption of sensor nodes. However, the sensor node is inevitable to be out of service once its limited battery energy is exhausted. To address this challenge, researchers have explored technologies to power sensor nodes by the ambient energy harvested, such as solar, wind, vibration, thermoelectric power, and radio frequency power, since the early 2000s (Adu-Manu et al. 2018). Due to the dynamic feature of energy harvesting, it is important to carefully design the energy management, especially the communication energy, to guarantee systems performance, such as connectivity, throughput, and delay (Pantazis and Vergados 2007).

In energy-harvesting WSNs, scheduling policies greatly depends on the harvested energy stored in the sensor node. A mathematical framework for energy harvesting sensor node scheduling is proposed in Lei et al. (2009), where different energy storage states are modeled as discrete-time Markov chains. Data packets with high priorities are preferred to be transmitted when energy storage is low. Under causality constraints on both data arriving process and energy harvesting process, Yang and Ulukus

(2012) studied optimal packet scheduling to minimize the transmission time for data packets by adaptively controlling the transmission rate and power. By considering the resource-limited hardware of energy harvesting sensor nodes, Liang et al. (2018) proposed a threshold-based scheduling policy for energy harvesting sensor networks to maximize its expected reward, which approaches the theoretical offline upper bound.

Foundations

An energy harvesting sensor node is composed of a microcontroller, a wireless transceiver, an energy harvester with storage, and multiple sensing units, as illustrated in Fig. 1. The sensor node converts harvested energy into electrical energy and store it in a finite-size energy storage for future data transmissions. Those sensed/generated data packets are stored in a memory structure and will consume some harvested energy during transmission. The hardware of both data memory and energy storage are size-limited. A data packet is transmitted only when there is enough energy stored/harvested. Under this causality constraint, data packets transmission scheduling at energy harvesting sensor node must be carefully managed.

A general system model for energy harvesting sensor node scheduling is presented in Fig. 2, where both data generation-transmission process and energy harvesting-consumption process are modeled as two independent dynamic queueing processes. Each successful transmission of a data packet will gain some rewards, whose value may be evaluated based on different performance metrics of interest (Ku et al. 2016), including transmission completion time, data throughput, outage probability, mean delay, message importance, quality of coverage, etc. An optimal scheduling policy aims to maximize the average transmission reward of the energy harvesting WSNs. Based on whether the knowledge of energy and data arrivals is available or not, packet scheduling policies can be categorized into *offline* scheduling and *online* scheduling:

Energy Harvesting Sensor Node Scheduling in Wireless Sensor Networks, Fig. 1 Architecture of an energy harvesting sensor node in wireless sensor networks

Energy Harvesting Sensor Node Scheduling in Wireless Sensor Networks, Fig. 2 System model for energy harvesting sensor node scheduling

- The *offline* scheduling assumes full knowledge of energy and data arrivals in the coming future and aims to develop an optimal scheduling policy for energy harvesting WSNs (Yang and Ulukus 2012). The study provides a theoretical optimal scheduling in energy harvesting WSNs by maximizing a certain short-term reward over a finite time horizon. In general, such kind of optimization problems can be solved by convex optimization techniques. The study of *offline* scheduling not only guides the design and deployment of WSNs but also provides an upper bound for further *online* scheduling studies.
- The *online* scheduling only has knowledge of current and past system status and tar-

gets to be implemented in real field deployment of WSNs. In order to perform real-time scheduling, threshold-based scheduling policies are widely adopted for *online* scheduling (Liang et al. 2018). Specifically, for each energy storage state, a corresponding transmission reward threshold is pre-computed and stored in a look-up table. Before each transmission, the sensor node searches for the corresponding threshold based on its energy storage state and only transmits a packet when its reward value is above the threshold. Due to the discrete nature of reward value thresholds, stochastic optimization techniques are used to maximize the long-term rewards of the energy harvesting WSNs.

Key Applications

Energy harvesting sensor node scheduling is fundamental in every energy harvesting WSN, which helps improve system performance metrics of interest, such as throughput, delay, and data importance.

[Ambient power technology](#); [Energy scavenging technology](#); [Power harvesting technology](#); [Wireless recharging technology](#)

Definitions

Energy is an important resource in wireless sensor networks since it determines the operation performance of sensors, i.e., data sensing, data processing, and data transmission. For the long-term applications, the power supply is one of the most important issues should be addressed since a fixed utility supply and/or manual battery changing may not be technically and economically viable. To address the power supply issue with the goal to obtain perpetual and unattended networks, energy harvesting technologies, which can harvest energy from energy sources in the surroundings (i.e., solar power, thermal energy, wind energy, kinetic energy, and electromagnetic energy), have been recently introduced to power the sensor nodes and thus achieve the goal of perpetual network operation. This kind of wireless sensor networks is known as rechargeable sensor networks or energy harvesting sensor networks.

Background

Generally, a wireless sensor network is composed of a large number of static sensor nodes with low-power device and limited processing capabilities to collect environment information. Each sensor node typically has three basic functions: (i) data sensing for acquiring environment information, (ii) data processing for processing the sensed data locally, and (iii) wireless communication for receiving and transmitting data. All of these functions are energy-consuming, especially in the large-scale and long-distance transmission wireless sensor networks. With development of wireless sensor networks, the need to extend the lifetime of wireless sensor networks becomes more and more urgent. Low-energy consumption technologies have been developed to prolong the lifetime of sensor nodes. However, low-energy consumption technologies cannot fundamentally solve the problem of insufficient energy in wireless sensor networks since a lot of applications require the sensor nodes can fulfill their requirements for a long duration (i.e., several months or several years) (Niyato et al. 2007; Shaikh and Zeadally 2016). Furthermore, it is very difficult, even impossible, to replace the batteries due to the difficult and hostile deployment terrain or large amount of sensors. As battery-powered sensor nodes are not feasible for long-term applications, energy harvesting technologies have been recently introduced to achieve the goal of perpetual network operation (Adu-Manu et al. 2018).

Since the energy sources are made up of different forms of ambient energy, there is no one solution that would fit all of applications. To satisfy various requirements of applications, many different types of energy harvesting systems have been designed. Generally, energy harvesting systems consist of: energy collection elements, conversion hardware and power conditioning, and storage devices as shown in Fig. 1. Energy collection elements determine the amount of energy that can be harvested. Conversion hardware and power conditioning convert the harvested energy to the electricity and conditioned to an appropri-

ate form for either charging the system batteries or powering the sensor node directly. Storage devices reserve the unused harvested energy for future use and power the sensor nodes if needed. The power densities of some common energy sources are shown in Table 2. Based on the requirements of applications, how to design the energy harvesting system (includes selections of energy source, energy collecting and conditioning circuit, and energy storage) and its corresponding energy management scheme is important. In the following part, some energy harvesting technologies are introduced based on energy sources and applications.

Energy harvesting sensor nodes can harvest ambient energy from sources in the surroundings, and store the harvested energy in the batteries for future use, such that sensor nodes can work perpetually. Normally, different ambient sources have different features and different energy harvesting technologies. For example, solar energy collected by the solar panel is predictable and non-controllable. Radio Frequency (RF) energy collected by the RF receiver is predictable and controllable. Some common energy sources and their corresponding characteristics are shown in Table 1.

Energy Harvesting Wireless Sensor Networks

Some common energy harvesting wireless sensor networks are introduced as follows.

RF-Based Energy Harvesting Wireless Sensor Networks

RF-based energy harvesting technology is one of the most popular energy harvesting technologies due to its predictable and controllable features. For RF-based energy harvesting sensor networks, the sensor nodes collect the energy carried by radio waves and convert it to DC power to power themselves. There are several approaches to convert the RF signals into DC power (i.e., single-stage vs. multistage). The selection of approaches

wireless sensor networks for environmental monitoring applications. A survey on wireless networks using RF energy harvesting has been summarized in Lu et al. (2015) and Alsaba et al. (2018). Furthermore, there exist a lot of works on circuit design, communication protocols, and operation design (Shu et al. 2017; Ren et al. 2018; Mouapi and Hakem 2018). RF-based energy harvesting wireless sensor networks are suitable for the application in urban and suburban areas due to the large amount of ambient energy sources and the controllable feature.

Solar-Based Energy Harvesting Wireless Sensor Networks

Solar-based energy harvesting technology is another popular energy harvesting technology due to its predictable and abundant features in the environment. There are two main approaches for converting sunlight into usable energy: thermal conversion and photovoltaic conversion. Photovoltaic conversion is more popular due to its higher-power density. There are a lot of factors that affected solar energy efficiency, i.e., cloud cover, sun intensity, relative humidity, and heat buildup. Due to the limitations of solar energy harvesting systems during the night, developers must ensure the highest possible efficiency during

day light hours to guarantee the viability of solar power.

Recently, Solar-based wireless sensor networks have been widely explored. A survey on the solar-based energy harvesting applications can be found in Sharma et al. (2018). Also, there exist a lot of works on the design of sensor nodes and the optimization algorithms/protocols to improve the network performance (Zhang et al. 2016, 2017; Wang et al. 2018). The solar-based energy harvesting wireless sensor networks are suitable for environmental monitoring applications due to its abundance in the environment.

Wind-Based Energy Harvesting Wireless Sensor Networks

Wind-based energy harvesting technology is a good alternative power source due to its high-energy density and abundance in the environment. As a form of kinetic energy, it can be collected by (micro) wind turbine to power the sensor nodes. Due to its unpredictable and non-controllable features, the energy supply always is fragile and unreliable. There exists a lot of works on the design of wind-based energy harvesting system and optimization of the network operation (Sardini and Serpelloni 2011; Ma et al. 2014; Porcarelli et al. 2015). Due to the non-controllable and unpredictable features of wind energy, to ensure the network performance, wind energy always is designed with other energy sources; some applications can be found in the following hybrid energy-harvesting systems.

Thermal-Based Energy Harvesting Wireless Sensor Networks

Thermal energy harvesting is based on the fact that when there is a temperature difference between two conducting materials, an electric current is generated. For Thermal-based sensors, both the environmental requirements and the thermoelectric materials are demanding. There exist some environmental studies on thermal powered sensor nodes, i.e., a thermoelectric generator (TEG) was mounted to a sheeps collar

to collect the temperature gradient between the sheep body and the ambient environment (Woiias et al. 2014), thermal energy harvesting between the air/water interface for powering sensor nodes (Zhou et al. 2014). Typically, thermal harvesting efficiency is 5–6%, which is low and becomes a major hindrance for its widespread adoption. Thermal energy harvesters are more suitable for large-scale power generation such as steam turbines (Shaikh and Zeadally 2016).

Human-Based Energy Harvesting Wireless Sensor Networks

Human-based energy harvesting technologies can be categorized as activity-based energy harvesting and inherent physiological parameters-based energy harvesting. Human-based energy harvesting sensor nodes can harvest energy from human activities (i.e., locomotion or changes in finger position, body heat, blood flow, movement, and heartbeat) and convert the collected energy into the available power to maintain their operations. In recent years, Wireless Body Area Network (WBAN) has been receiving a lot of attention recently (Mukhopadhyay 2015; Thielen et al. 2017; Rault et al. 2017).

Hybrid Energy-Harvesting Systems

Due to different features of different energy sources, combining multiple types of energy harvesters in a single sensor node can achieve better performance. There exists several common hybrid energy harvesting systems:

1. Solar/Thermal Systems in organic fertilizer plant, which consists of solar panels and TEG as energy converters (Chottirapong et al. 2015).
2. Solar/Thermal/Electromagnetic Systems to improve the performance of autonomous wireless network nodes (Virili et al. 2015, 2016).
3. Solar/wind Systems to build energy-autonomous sensing systems (Cammarano et al. 2016; Spenza et al. 2012).

[Energy harvesting and consumption for nanoscale terahertz communication](#); [Energy modeling for nanonetworks in the terahertz band](#)

Definitions

Energy modeling for nanoscale terahertz communication is required to investigate the relationship between energy harvesting and consumption in nanoscale terahertz communication and analyze the trade-off between them by jointly considering the constraints of nanonetworks and the peculiarities of terahertz communications, in order to achieve perpetual nanonetworks.

Historical Background

Nanotechnology is enabling the development of novel devices in the order of a few cubic micrometers in size, which can accomplish only very simple tasks (Akyildiz and Jornet 2010). Due to the very limited abilities of individual nanodevice, communication among nanodevices will expand the potential applications of single nanodevice through collaboration. The resulting nanonetworks will be able to boost the range of applications of nanotechnology in biomedical, environmental, and military fields, such as intrabody health monitoring systems, distributed air pollution control, and nanosensor networks (Krishnaswamy et al. 2010). Two main alternatives for communication in the nanoscale have been considered, i.e., molecular communication and electromagnetic

communication, respectively. In detail, molecular communication is defined as the transmission and reception of information encoded in molecules, while electromagnetic communication is defined as the transmission and reception of electromagnetic radiation from nanodevices using novel nanomaterials (Akyildiz and Jornet 2010). In this chapter, electromagnetic communication among nanodevices in the terahertz band is considered and introduced.

According to the extremely small size of nanodevices, scaling a metallic antenna down to a few hundred nanometers would impose the use of very high operating frequencies, thus, drastically limiting the communication range of nanodevices. Alternatively, graphene and its derivatives, such as carbon nanotubes and graphene nanoribbons, can be used to develop nanoantennas able to radiate at much lower frequencies. This frequency band, named Terahertz (THz) Band, spans the frequency range from 0.1 to 10.0 THz (Jornet and Akyildiz 2011). For the time being, due to the strict constraints of a single nanodevice in terms of size and energy, no integrated technology has been presented to generate a high-power carrier frequency in the THz band. As a result, the traditional wireless communication mechanisms on the basis of continuous transmission signals may be not suitable for nanonetworks with limited hardware. Inspired by the huge bandwidth provided by the THz band, new pulse-based communication mechanisms have been envisioned as the candidates for nanonetworks by the exchange of a few femtoseconds-long pulses. Moreover, the energy requirement on the transmission is relaxed by distributing short pulses over the time rather than continuous signals (Yao et al. 2015).

On the other hand, the very limited energy stored in the nanobatteries is another major challenge in nanonetworks. Therefore, energy harvesting system has been considered to provide energy for nanodevices (Wang 2008). Unfortunately, conventional energy harvesting systems, such as solar energy, or wind power, cannot be adopted owing to the extremely small size of nanodevices, just several cubic micrometers (Sude-

valayam and Kulkarni 2011). Recently, piezoelectric nanogenerators have been proposed to recharge the nanodevices (Yao et al. 2018). In addition, some works considered the energy consumption process of electromagnetic communication in the THz band and even for multi-hop nanonetworks in the aspect of MAC-layer or Network-layer.

Foundations

One of the major bottlenecks in nanonetworks is the very limited energy that can be accessed by nanodevices. To achieve perpetual data transmission, it is required to investigate in-depth the relationship between energy harvesting and consumption and the underlying constraints in nanonetworks (Yao et al. 2015).

Energy Harvesting Modeling

In nanonetworks, the lifetime of each nanodevice is mainly dependent on the limited energy provided by the nanobatteries with a very small size. Hence, it is highly desirable that nanodevices are enabled to be self-powered without the use of nanobatteries. In the last decade, nanotechnology-enabled methods for converting mechanical energy into electrical energy by using the piezoelectric effect of zinc oxide nanogenerators have been explored (Wang and Song 2006). Due to the low energy consumption of nanodevices during the transmission of information in the THz band, especially over a short distance, the resultant energy harvested from the environment could be sufficient to power the nanodevices.

According to the simplified circuit model of piezoelectric nanogenerator as shown in Fig. 1, through several cycles of charging, the voltage of the nanocapacitor rises up, and the harvested energy is also stored in the nanocapacitor to power other modules in a nanodevice (Jornet and Akyildiz 2012). The maximum energy $E_{cap} - \max$ (n_{cyc}) stored in the nanocapacitors after a number of cycles n_{cyc} can be computed as a function of the total capacitance C_{cap} and voltage V_{cap} of the array of nanocapacitors:

Energy Modeling for Nanoscale Terahertz Communication, Fig. 1 Simplified circuit model of piezoelectric nanogenerator, which includes an array of ZnO nanowires

(i.e., electric source V_g), a rectifying circuit, and an ultra-nanocapacitor

$$E_{cap-\max}(n_{cyc}) = \frac{1}{2} C_{cap} (V_{cap}(n_{cyc}))^2. \quad (1)$$

For a particular nanodevice, its total capacitance C_{cap} and voltage V_{cap} are always predefined; then the required number of charging cycles n_{cyc} can be obtained when the energy consumption for transmission is determined, which will be comprehensively investigated in the next sections. Finally, the energy harvesting rate λ_{harv} in Joule/second at which the capacitors are charged can be obtained as follows (Jornet and Akyildiz 2011; Yao et al. 2015):

$$\lambda_{harv} = \frac{1}{t_{cyc}} \cdot \frac{\partial E_{cap}}{\partial n_{cyc}} = \frac{V_g \cdot \Delta Q}{t_{cyc}} \cdot \left(e^{\left(-\frac{\Delta Q \cdot n_{cyc}}{V_g C_{cap}}\right)} - e^{\left(-2\frac{\Delta Q \cdot n_{cyc}}{V_g C_{cap}}\right)} \right) \quad (2)$$

where ΔQ refers to the amount of electric charge obtained from one cycle, $\frac{\partial E_{cap}}{\partial n_{cyc}}$ refers to the energy increase of the nanocapacitors in each cycle, and t_{cyc} is the required time of one charging cycle, i.e., the time between two consecutive cycles. If the compress-release cycles are created by an artificially generated vibration source, the value of t_{cyc} corresponds to the inverse of the frequency of the vibration source. In this paper, the minimum value of n_{cyc} can be calculated to guarantee the required energy for transmission in the THz band.

Energy Consumption Modeling

Due to the constrained energy in nanodevices, short pulses cannot be emitted in a burst. Hence, new information encoding and modulation mechanisms for nanonetworks are required urgently. Furthermore, in order to take advantage of the large bandwidth of the THz band, pulse-based communication paradigm (such as TSOOK) has been recommended in (Jornet and Akyildiz 2011, 2014; Yao et al. 2015), which is based on the exchange of very short pulses spread in time. In detail, a logical “1” is transmitted by a short pulse (one hundred femtoseconds), and a logical “0” is transmitted as silence, i.e., nanodevices remain silent when a logical “0” is transmitted.

In order to evaluate the consumed energy in the transmission and reception of one packet, when the length of one packet is N_{bits}^y , the consumed energy in the transmission and reception of one pulse are E_{pul-t} and E_{pul-r} , respectively. Consequently, the consumed energy for transmitting and receiving one packet can be given by

$$E_{tx}^y = N_{bits}^y W_y E_{pul-t}, \quad (3)$$

$$E_{rx}^y = N_{bits}^y W_y E_{pul-r}, \quad (4)$$

where $y = p$ or $y = d$ stands for the calculation of one probing packet and one data packet, respectively. W_y refers to the coding weight, which is adaptive to different coding algorithms or parameter optimizations (Yao et al. 2015).

For simplicity, the general energy consumption model in nanonodes by considering the

Energy Modeling for Nanoscale Terahertz Communication, Fig. 2 The general process of energy state model in ECP mechanism, which considers the energy harvesting-consumption process based on extended Markov chain

energy harvesting-consumption process based on extended Markov chain approach (Jornet and Akyildiz 2012) is shown in Fig. 2, and the associated notations are listed in Table 1. Each state in the model corresponds to an energy state of nanonode. The red dashed box refers to a set of states that the nanonode works in the probing mode. The solid lines represent the energy harvesting process, while the other lines represent the energy consumption process. The short dashed lines represent the energy consumption processes of sending one data packet and receiving its feedback, which is denoted as λ_{tx} . The dash-dotted lines represent the energy consumption processes of receiving one data packet or one probing packet, which is denoted as λ_{rx} . The double-dash dotted lines represent the energy consumption processes of sending one probing packet and receiving

its feedback, which is denoted as λ_{px} . The detailed operations of the proposed model for electromagnetic nanonetworks are conducted as follows:

In order to increase the successful transmission probability of data packets and reduce the energy consumption of communication, this model divides all energy states into two parts as shown in Fig. 2. On the one hand, each nanonode will keep harvesting energy and enter the probing mode only as its energy value is beyond the probing mode energy threshold δ . On the other hand, in the probing mode, one probing packet will be transmitted to detect the channel condition at first. Data packet will be sent out only after the probing packet is transmitted successfully.

In general, two conditions in the energy state model are considered. The first condition is that nanonode only keeps harvesting energy without

Energy Modeling for Nanoscale Terahertz Communication, Table 1 Notations of the symbols in Fig. 2

Symbol	Description
$\{E\}$	The energy state when its energy value is E
E_0	Energy value of initial state
E_{PR}	Energy consumption of receiving one packet, which equals to the data receiving energy threshold τ
E_{PT}	Energy consumption of sending one packet and receiving its feedback, which equals to the data sending energy threshold γ
E_{PE}	Energy consumption of sending one probing packet and receiving its feedback
E_{max}	Energy saturated value
$E_{PT} + E_{PE}$	Energy threshold of the probing mode, δ
E_{PP}	An energy value between $E_{PT} + E_{PE}$ and E_{max}
λ_e	Energy harvesting rate
$\lambda_{tx}(t)$	The transmission rate of one data packet
$\lambda_{rx}(t)$	The reception rate of one data packet
$\lambda_{px}(t)$	The transmission rate of one probing packet

transmitting or receiving any packet from the initial energy state $\{E_0\}$ to the saturated energy state $\{E_{max}\}$. The second condition is that nanonode needs to transmit or receive data packets while harvesting energy. More specifically, there are two modes in the second condition as follows:

- Mode 1 (General Mode): From the beginning of initial energy state $\{E_0\}$, nanonode captures energy and receives packets (when necessary) rather than transmits any packet until it reaches the maximum energy E_{max} and enters the saturated energy state $\{E_{max}\}$. Moreover, the nanonode will not receive packets until the energy is beyond the data receiving energy threshold τ .
- Mode 2 (Probing Mode): While harvesting energy, nanonode needs to transmit data packets as well, if nanonode wants to transmit data in a certain state such as $\{E_{PP} + E_{PE}\}$. Firstly, its stored energy has to reach the energy threshold δ of probing mode. After sending out one probing packet, nanonode consumes the energy E_{PE} and enters into the energy state $\{E_{PP}\}$. According to the received feedback from the receiver after the probing packet transmitted, there are two cases:
 1. Case 1: If the feedback of probing packet is a negative acknowledgment

(NAK) or timeout, i.e., the channel is in bad condition, and nanonode needs to retransmit the probing packet. It is worth to note that nanonode has to determine whether its current energy reaches the energy threshold δ before detecting the channel by using the probing packet. As the energy is sufficient for channel detection, the probing packet will be sent out. The probing process continues until an ACK is received or its maximum number of retransmission is reached. Otherwise, the nanonode needs to harvest energy until the energy threshold δ , and then channel detection is performed again.

2. Case 2: If the feedback of probing packet is an active acknowledgment (ACK) and the energy of nanonode is beyond the energy threshold γ , then one data packet will be transmitted. This process will consume the energy E_{PT} , and let the nanonode move to the state $\{E_{PP} - E_{PT}\}$. For the feedback of the data packet, if it is an ACK, i.e., the data packet is transmitted successfully, the nanonode can start a new data transmission or end. If it is a NAK, the nanonode will enter into the probing mode again, until the data packet is transmitted successfully or its maximum number of retransmission is reached.

Key Applications

Energy modeling for nanoscale terahertz communication is fundamental for electromagnetic networks in the microscale or nanoscale applications where the energy is extremely limited or constrained.

Energy-Aware and Throughput-Improved Route Selection for Wireless Multi-hop Networks

Yifei Wei

School of Electronic Engineering, Beijing University of Posts and Telecommunications, Beijing, China

Synonyms

[Routing protocol](#)

Definitions

As a means of providing instant networking to a group of devices which may not be within the

transmission range of one another without the support of any infrastructure, wireless multi-hop self-organizing networks are becoming increasingly popular, such as mobile ad hoc network (MANET), wireless sensor networks (WSNs), and wireless mesh networks (WMNs). Wireless multi-hop transmission is a promising wireless solution for numerous applications Ian et al. (2005), e.g., wireless sensor networking, broadband home networking, wireless campus networking, wireless enterprise networking, temporary emergency communications, intelligent transportation, etc. Despite the availability of many routing protocols for multi-hop wireless networks, the design of new routing metrics is still an active research topic in order to improve the network performance. The most frequently used metrics so far for routing protocols include hop count and link quality. However, they are far from satisfying the need of end users because finding an optimal route depends on the objectives and network characteristics.

Mobile devices are generally battery-powered and thus have limited energy resource that constrains the lifetime of the network. It is imperative that energy conservation is considered across all layers of the protocol stack in order to optimize the network energy consumption and prolong the lifetime of the network. Many theoretical studies show that energy consumption can be significantly reduced using energy-aware routing protocols compared to fixed-power minimum-hop routing protocols, and therefore the task of this subject is to design energy-aware and throughput-improved routing protocols for wireless multi-hop self-organizing networks.

Minimum Hop Count Routing Protocols

Most existing wireless routing protocols use hop count as the metric to choose the shortest path between source node and destination node. The traditional routing protocols such as dynamic

source routing (DSR) and ad hoc on-demand distance vector (AODV) are based on shortest path algorithms (or minimum hop count). In hop-count routing protocol such as AODV, source node sends a packet called routing frame in order to find the shortest path to the destination node. All the neighbor nodes of the source node will receive and forward this routing frame. Every routing frame has a hop counter which is called time to live (TTL) and has an initial positive integer. The TTL is decremented by one as packet travels one hop. When the TTL is reduced to zero, the routing frame will be discarded. After the destination node receives the routing frame forwarded by all its neighboring nodes, the destination node will pick up the routing frame with the highest TTL from the received routing frame to reply. The node that has forwarded the route request packet will form the shortest path from the source node to the destination node. After receiving the feedback, the source node will send information to the destination node according to this shortest path. This greedy hop-count routing protocol will lead every hops distance close to the nodes coverage radius. Also, one network with n connections, the routing frame will be re-transmitted n times if the source node does not know the way to destination node in the worst case. With the increase in nodes coverage radius, the number of connections between it and its neighbors will increase, which means that the times of retransmitting routing frame will increase. Even though, increase the radius of nodes will benefit the probability that finding a route from source node to destination node, too many times of retransmitting routing frame will increase the network overhead and possibility of routing loop which will influence other nodes extremely.

High-Throughput Routing Method

Minimum hop count routing protocols minimize the total number of transmissions required to send

Energy-Aware and Throughput-Improved Route Selection for Wireless Multi-hop Networks,

Fig. 1 Path selection options

a packet from source node to destination node. The minimum hop count routing metric is appropriate in single-rate wireless networks because every transmission consumes the same amount of resources. However, in multi-rate networks supporting the dynamic rate shifting scheme, the minimum hop metric has a tendency to select paths containing long-distance links that have low data rates and reduced reliability. Furthermore, the routing overhead will increase rapidly when the network topology changes frequently in mobile environment (Wei et al. 2010).

As is shown in Fig. 1, when the user equipment A want to communicate with the wireless access point D. According to the minimum hop count routing metric, the selected path will be $A \rightarrow E \rightarrow D$, which contains two long-distance links with data rates of 1 Mbps, respectively. Therefore, the whole path only provides the data rate of 500 Kbps and results in lowered network throughput and increased packet delay. To take advantage of multi-rate capabilities of wireless networks, we can select paths consisting of links with high data rates and better signal quality, but not necessarily with minimum number of hops. For example, when selecting the path of $A \rightarrow B \rightarrow C \rightarrow D$, the data rate can be more than 1 Mbps. Many works have been dedicated to providing high-throughput routing strategies. The previous work in Wei et al. (2011) optimizes the network throughput through relay selection under the finite-state Markov channels models. Fan (2004) proposes using MAC delay as a metric when choosing high-throughput routes in AODV.

The authors in Seok et al. (2003) introduced a multi-rate aware sublayer to find high data rate links.

Energy Hole Problem

Traditional routing protocols are local optimum and will produce the energy hole problem (Ren et al. 2016). There are two kinds of energy hole problems in multi-hop wireless networks: one happens in WSNs and another exists in wireless distributed networks.

The WSNs is known for monitoring the environment, where a sensor may act as an information detection device or a relay and a Sink node is used as the information collector. It is inconvenient or even infeasible to recharge or replace the batteries of sensors in WSNs. Traditional routing algorithm is based on the local optimization rather than global optimization. Therefore, sensors around the Sink node tend to run out of battery easily due to heavy traffic flow, which limits the network lifetime dramatically, and this problem is called the energy hole problem. The energy hole problem in WSNs can be solved by advanced routing protocol and power control (Guan et al. 2010).

In wireless distributed networks, nodes located near the center area of a region are more likely to be selected as a relay node. Therefore, the nodes in the center area usually relay too much data and run out of energy very quickly. For this reason, after several rounds of data

transmission, there would be an energy hole at the center of the convex region. Under the greedy routing algorithm, the energy hole will speed up the energy consumption of its nearby nodes, resulting in the energy hole expanding. The energy hole problem can also lead to the source node failure to reach the destination node, which is called routing failure. The energy hole problem in wireless distributed networks can be solved by topology control from a global perspective (Guo et al. 2014; Ao et al. 2014).

Traffic engineering; Software-defined wireless networking; In-network caching; Quality of experience

Definitions

Wireless Edge Caching (WEC) refers to that in-network caching is enabled at the edge of wireless networks such as access point and edge router. Software-defined wireless networking (SDWN) refers to that software-defined networking (SDN) is adopted in wireless networks to steer the traffic and in-network caching is a promising technology in the next-generation wireless networks. The quality of experience (QoE) of video streaming services mainly includes video resolutions, buffering delays, and stalling events. Then, it is important to consider the enhancement of the caching performance in wireless networks with considering QoE by utilizing the SDWN. First, bandwidth provisioning in SDWNs should be content-aware, which means it should assign network resources to users based on the caching status and the improvement of the QoE. Second, to enhance the hitting ratio of caches (utilization), caching strategies should be proactive according to the current traffic and resource status, behaviors of users, as well as the requirements of the QoE. Third, since video SDN flows from service providers usually have minimum require-

ments, the overall QoE performance of the network needs to be guaranteed.

Historical Background

Bandwidth provisioning (flow control) of SDWNs is studied in Farmanbar and Zhang (2014) and Dao et al. (2015) through traffic engineering. The authors of Farmanbar and Zhang (2014) propose a multipath traffic engineering formulation for downlink transmission considering both backhaul and radio access constraints. Moreover, the link buffer status is used as feedback to assist the adjustment of flow allocation. Based on Farmanbar and Zhang (2014), the authors of Dao et al. (2015) extend flow control of SDWNs to real-time video traffic specifically. This research proposes an online method to estimate the effective rate of video flows dynamically. Min flow rate maximization of SDWNs is investigated in Liao et al. (2014) with jointly considering flow control and physical layer interference management problem using weighted-minimum mean square error algorithm.

In the line of caching at mobile networks, the authors of El Bamby et al. (2014) formulate a delay minimization problem by optimally caching contents at the SBS. This research firstly clusters users with similar content and then deploys a reinforcement learning algorithm to optimize its caching strategy accordingly. Liu and Lau (2013) propose a scheme that BSs opportunistically employ cooperative multiple-input multiple-output (Coop-MIMO) transmission by caching a portion of files so that MIMO cooperation gain can be achieved without payload backhaul, while Dai and Yu (2014) and Tao et al. (2016) propose to utilize caching for releasing part of fronthaul in C-RAN. Unfortunately, the research does not take the real-time mobile network and traffic status into account. In Abboud et al. (2015), the proposed cache allocation policy considers both the backhaul consumption of small BSs (SBSs) and local storage constraints. The authors of Liang and Yu (2016) introduce in-network caching into SDWNs to reduce the latency of

backhaul, but cache strategies are ignored in this study. Poularakis et al. (2015) introduces dynamic caching into BS selection from the aspect of energy saving. In Siris et al. (2014), dynamic caching is proposed to consider the mobility of users, but it focuses more on the cache resource and relationship between nodes. Network resources, such as the backhaul capacity and spectrum, are not discussed in this research.

Video quality adaptation with radio resource allocation in mobile networks (especially, long-term evolution (LTE)) is studied in a number of studies. The authors of Seufert et al. (2015) provide a comprehensive survey on quality of experience of HTTP adaptive streaming. Joint optimization of video streaming and in-network caching in HetNets can be traced back to Golrezaei et al. (2012). This research suggests that SBSs form a wireless distributed caching network that can efficiently transmit video files to users. Meanwhile, Ahlehagh and Dey (2014) take the backhaul and the radio resource into account to realize video-aware caching strategies in RANs for the assurance of maximizing the number of concurrent video sessions. The authors of Zhu et al. (2013) move the attention of in-network video caching to the core networks, instead of RANs, of LTE. To utilize new technologies in next-generation networks, Liu and Lau (2015) study the quality of video in next-generation networks. Pedersen and Dey (2016) conduct a comprehensive research that investigates opportunities and challenges of combining the advantages of adaptive bit rate and RAN caching to increase the video capacity and QoE of wireless networks. Another research combining the caching and video service is Yu et al. (2016), where collaborative caching is studied with jointly considering scalable video coding. However, RAN and overall video quality requirements are not considered.

Foundations

Generally speaking, SDWNs can enable the reduction of complexity and cost of networks, equip programmability into wireless networks, accelerate evolution of networks, and even further catalyze fundamental changes in the mobile ecosystem (Chen et al. 2015). The success of

Wireless Networks, Fig. 1**
Network architecture of the
cache-enabled SDWN

E

the SDWN will depend critically on our ability to jointly provision the backhaul and radio access networks (RANs) (Liao et al. 2014).

WEC, as an extension of *in-network caching* that can efficiently reduce the duplicate content transmission (Ahlgren et al. 2012; Liang et al. 2015), has shown that access delays, traffic loads, and network costs can be potentially reduced by caching contents in wireless networks (Liu et al. 2016). To successfully combine caching and wireless networks, significant works (e.g., Li et al. 2015; Tao et al. 2016) have been done concerning utilizing and placing contents in the caches of base stations (BSs).

Thus, the network performance should be jointly optimized QoE of video streaming, bandwidth provisioning, and caching strategies in SDWNs with limited network resources and QoE requirements. To decrease the content delivery latency and improve the utilization of the network resources and caches, BSs are requested to retrieve data in advance dynamically according to the behaviors of users, the current traffic, and the resource status. To cope with the limited resources and the quality of service requirements, the caching problem is decoupled from the bandwidth provisioning problem by deploying the dual-decomposition method.

As shown in Fig. 1, a central SDN controller is deployed to control the network including

caching strategies and bandwidth provisioning. BSs connect to the CN through wired backhaul links with fixed capacities (e.g., bps). A content server is physically located at a core router (content delivery networks) in the CN or the source server. Moreover, as shown in Fig. 1, some BSs (e.g., SBSs) connect to the CN through MBSs. Without loss of generality, each BSs may have multiple links to be connected in the networks (e.g., SBS 3 in Fig. 1). To improve the caching performance, BSs can proactive cache contents that may be requested users. The probability that a cached content in BS j will be used by user i is assumed to be π_{ij} . In practice, π_{ij} depends on the user mobility pattern (Qiao et al. 2016) (current location, moving velocity and direction, and unpredictable factors) and the popularity of the content (Siris et al. 2014). The research about the behaviors of users has attracted great interests from both academia and industry (Yu and Leung 2001). Necessary information for processing prediction can come from real-time data (e.g., UEs and RANs) and historical data (e.g., users database). Fortunately, the improvement of machine learning and big data technologies can help the management and the control of mobile networks (He et al. 2016, 2017). By using those advanced techniques, the network is able to have a deeper view of the traffic and the coverage from the huge volume of historical data, which may

help the network to enhance the accuracy of the prediction.

By using the spare backhaul bandwidth to cache content to BSs before users actually served (or potentially continued being served) with those BSs (or actually request the content), BSs adaptively replace content in caches of BSs while optimizing the bandwidth provisioning and the video resolution selection. Moreover, caches and bandwidth are actually belonging to different layers of the network. Usually, flow bandwidth is restricted by physical resources (provisioned by media access control layer), and the video resolution depends on the achievable data rate. Joint optimization of video rate and flow bandwidth are studied in cross-layer design schemes (Yu and Krishnamurthy 2006). Differently, in-network cache is placed at the network layer or even higher layer. In addition, scheduling of the caching can be acting in a longer time period compared to flow scheduling.

Firstly, in the control plane, the SDN controller updates the network status according to feedback from BSs, then predict the users' behaviors to calculate $\{\pi_{ij}\}$. By using this information, the SDN controller evaluates and calculates the provisioned bandwidth and caching strategy for each flow i and BS j . After this, the SDN controller sends the control information to selected BSs and content source (the cloud center or the public networks). According to the control information, BSs and other network elements (e.g., potential routers) will update their SDN forwarding tables and perform resource allocation (e.g., cell association and scheduling). In the data plane, flows carrying contents requested by users can pass network elements selected by the control plane and to users.

Key Applications

The proposed scheme can be used to improve the QoE of multimedia transmission in the future wireless network. For example, this study can help the operator improve the QoE of video streaming in scenarios of cellular assisted-vehicle networks and high-speed trains in 5G.

Equalization Techniques for Single-Carrier Modulations

Michael Rice

Department of Electrical and Computer Engineering, Brigham Young University, Provo, UT, USA

Synonyms

[Inter-symbol interference](#); [Linear modulation](#); [Maximum likelihood sequence detection](#)

Definitions

Linear modulations use pulses to transmit data over a channel. Transmission through a nonideal channel (say, from multipath propagation) causes temporal spreading of the pulses. The temporal spreading of the pulses produces a phenomenon known as inter-symbol interference: the detection instant for a given symbol contains contributions from adjacent symbols. Equalization refers to the category of signal processing techniques designed to mitigate inter-symbol interference.

Introduction

Linear, single-carrier modulations are described by the complex-valued, low-pass equivalent pulse

train (Proakis 2008).

$$s_c(t) = \sum_{k=0}^{K-1} a_k p_c(t - kT_s) \quad (1)$$

where a_k is the k -th complex-valued symbol drawn from an alphabet $\mathcal{C}$ with M members and with $E_s = E\{|a|^2\}$, $p_c(t)$ is a unit energy pulse shape, and T_s is the symbol time (i.e., a new M -ary symbol is transmitted every T_s sec). The number of symbols is K where K may be infinite. In most cases, the pulse shape $p_c(t)$ is designed to satisfy the Nyquist no-ISI theorem:

$$\int p(t)p(t - kT_s) dt = \begin{cases} 1 & k = 0 \\ 0 & k \neq 0 \end{cases} \quad (2)$$

and is used to shape the power spectral density of $s_c(t)$.

When the pulse train is transmitted through a propagation medium described by the linear time-invariant system with impulse response $h_c(t)$, the pulse shape $p_c(t)$ may be altered by $h_c(t)$. The received signal is a pulse train based on the composite pulse shape $h(t) = p_c(t) * h_c(t)$. Including additive thermal noise, the received signal is modeled as

$$y_c(t) = \sum_{k=0}^{K-1} a_k h(t - kT_s) + z_c(t) \quad (3)$$

where $z_c(t)$ models the additive thermal noise and is a complex-valued zero-mean circularly symmetric normal random process with

$$E\{z_c(t + \tau) z_c^*(t)\} = 2N_0 \delta(\tau) \quad (4)$$

where $\delta(\tau)$ is the Dirac delta function. The situation is illustrated in Fig. 1. The problem is to estimate the sequence $a_0 \dots, a_{K-1}$ from $y_c(t)$.

If $h_c(t)$ is anything but a memoryless system, the composite pulse shape does not satisfy Eq. (2):

$$\int h(t)h(t - kT_s) dt \neq \begin{cases} 1 & k = 0 \\ 0 & k \neq 0. \end{cases} \quad (5)$$

Equalization Techniques for Single-Carrier Modulations, Fig. 1 The complex-valued, low-pass equivalent system considered for the equalizers

Because $h(t)$ does not satisfy Eq. (2), the usual matched filter detector outputs at $t = nT_s$ depend not only on the symbol a_n but also on temporally adjacent symbols. This dependency is a form of interference known as intersymbol interference (ISI). The goal of equalizers is to estimate the sequence $a_0 \dots, a_{K-1}$ from $y_c(t)$ in the presence of ISI.

Four broad approaches are described: maximum likelihood solutions in the section “[Maximum Likelihood Solutions](#),” filter-based equalizers in the section “[Filter-Based Equalizers](#),” adaptive equalizers in the section “[Adaptive Equalizers](#),” and blind equalizers in the section “[Blind Equalizers](#).”

Maximum Likelihood Solutions

The maximum likelihood (ML) solution applies to $y_c(t)$ a filter matched to $h(t)$ and uses T_s -spaced samples of the matched filter output with a sequence detector. The system that performs these functions is illustrated in Fig. 2. The output $r'_c(t)$ is given by

$$r'_c(t) = \sum_{k=0}^{K-1} a_k g(t - kT_s) + v_c(t) \quad (6)$$

where $g(t) = h(t) * h^*(-t)$ is the autocorrelation function of the composite pulse shape and $v_c(t)$ is a complex-valued wide-sense stationary circularly symmetric normal random process with autocorrelation function

$$E\{v_c(t + \tau) v_c^*(t)\} = 2N_0 g(\tau). \quad (7)$$

Equalization Techniques for Single-Carrier Modulations, Fig. 2

The complex-valued, low-pass equivalent system that represents the ML solution

It is customary to consider only pulse shapes and channels that produce an autocorrelation function $g(\tau)$ with support on $-LT_s \leq \tau \leq LT_s$ for some positive integer L . This consideration does not diminish the application of following results, because essentially all practical propagation channels are represented by linear systems with a finite-length impulse response.

The n -th T_s -spaced sample of $r'_c(t)$ is

$$r'_n \triangleq r'_c(nT_s) = \sum_{k=0}^{K-1} a_k g_{n-k} + v_n \quad (8)$$

where $g_m \triangleq g(mT_s)$ and $v_n \triangleq v_c(nT_s)$. Equation (8) represents an entirely discrete-time system: the discrete-time inputs are the symbols and the discrete-time outputs are the samples r'_n . The *equivalent discrete-time system* is illustrated by the block diagram in Fig. 3. The discrete-time autocorrelation function g_m has support on $-L \leq m \leq L$. In the figure, $G(z)$ is the z -transform of g_m

$$G(z) = \sum_{m=-L}^L g_m z^{-m}. \quad (9)$$

The noise sample v_n is the n -th sample in a complex-valued wide-sense stationary circularly symmetric normal random process with zero mean and autocorrelation function

$$E\{v_n v_m^*\} = 2N_0 g_{n-m}. \quad (10)$$

The equivalent system in Fig. 3 is informally called the “Ungerboeck Observation Model” after the first person to analyze it (Ungerboeck 1974). In the Ungerboeck Observation Model, the sequence of r'_n forms the input to a ML sequence estimator based on the Viterbi algorithm. The Viterbi algorithm is based on a trellis with M^L

Equalization Techniques for Single-Carrier Modulations, Fig. 3 The equivalent discrete-time system corresponding to Fig. 2. This discrete-time model for the relationship between a_k and r'_n is informally known as the “Ungerboeck Observation Model”

states and uses the branch metric

$$J_U(a_n) = \text{Re} \left\{ a_n^* \left(2r'_n - g_0 a_n - 2 \sum_{m=1}^L g_m a_{n-m} \right) \right\} \quad (11)$$

for the symbol a_n connecting the state defined by $(a_{n-L}, \dots, a_{n-1})$ to the state defined by $(a_{n-L+1}, \dots, a_n)$.

In the Ungerboeck Observation Model (8), the noise samples accompanying the signal portion are correlated. It is usually preferred to perform sequence estimation in the presence of uncorrelated (white) noise samples. With uncorrelated noise samples, the branch metrics used by the Viterbi algorithm are more simple and the performance analysis is more straightforward. “Whitening” the noise sequence in Eq. (8) produces a discrete-time observation model informally known as the “Forney Observation Model,” after the first person to analyze it (Forney 1972).

The Forney Observation Model is derived from the Ungerboeck Observation Model as follows. The power spectral density of the noise term v_n in Eq. (8) is $2N_0 G(z)$. Noise whitening is based on the spectral factorization of $G(z)$. Because g_m is an autocorrelation function, it possesses conjugate symmetry: $g_{-m} = g_m^*$. Consequently, the $2L$ roots of the degree- $(2L+1)$

polynomial $G(z)$ defined in Eq. (9) also possess symmetry: $G(\rho) = 0 \Rightarrow G(1/\rho^*) = 0$. This means that each root inside the unit circle has a companion root outside the unit circle in the conjugate reciprocal position. Thus $G(z)$ may be written as

$$G(z) = F(z)F^*(1/z^*) \quad (12)$$

where $F(z)$ is the degree- $(L + 1)$ polynomial formed from the L roots of $G(z)$ inside the unit circle and $F^*(1/z^*)$ is the degree- $(L + 1)$ polynomial formed from the L roots of $G(z)$ outside the unit circle. Noise whitening is accomplished by passing r'_n through the anticausal IIR system $1/F^*(1/z^*)$ as illustrated in Fig. 4. The resulting output r_n is given by

$$r_n = \sum_{\ell=0}^L f_{\ell} a_{n-\ell} + w_n \quad (13)$$

where f_k for $k = 0, \dots, L$ is the k -th element of the inverse z -transform of $F(z)$, and w_n is a complex-valued wide-sense stationary circularly symmetric normal random process with zero mean and autocorrelation function

$$E\{w_n w_m^*\} = 2N_0 \delta_{n-m} \quad (14)$$

Equalization Techniques for Single-Carrier Modulations, Fig. 4 The equivalent discrete-time system known as the “Forney Observation Model”: (a) The relationship between the Forney Observation Model and the Ungerboeck Observation Model (Fig. 3); (b) The “Forney Observation Model”

where δ_{n-m} is the Kronecker delta function. The sequence of r_n in Eq. (13) forms the input to a ML estimator using the Viterbi algorithm based on M^L states and using the branch metric

$$J_F(a_n) = \left| r_n - \sum_{\ell=0}^L f_{\ell} a_{n-\ell} \right|^2 \quad (15)$$

for the branch connecting the state defined by $(a_{n-L}, \dots, a_{n-1})$ to the state defined by $(a_{n-L+1}, \dots, a_n)$.

In summary, the maximum likelihood detector for ISI channels is a maximum likelihood *sequence* estimator, usually realized by the Viterbi algorithm. A straightforward application of the maximum likelihood principle produces the equivalent discrete-time system known as the “Ungerboeck Observation Model” given by Eq. (8) and illustrated in Fig. 3. The “whitened” version is called the “Forney Observation Model” given by Eq. (13) and illustrated in Fig. 4b. Both achieved the same probability of error performance (Ungerboeck 1974). The differences lie in where the computational complexity resides. The branch metrics in the “Ungerboeck Observation Model” (11) require more arithmetic operations than the branch metrics in the “Forney Observation Model” (15). On the other hand, the “Forney Observation Model” requires a spectral factorization and a whitening filter operation. Both operate on a trellis with M^L states. Because the size of the trellis grows exponentially with L , the length of the composite filter, the computational complexity can be prohibitive. For this reason, nonoptimal approaches based on FIR filters are popular.

Filter-Based Equalizers

Equalizers based on discrete-time filters are used when the length of the equivalent discrete-time filter is too long for the ML approach to be computationally practical. Historically, finite-length impulse response (FIR) discrete-time filters are used because, unlike infinite-length impulse

response (IIR) discrete-time filters, the filter operation may be pipelined for fast operation, an important consideration in high data-rate applications.

FIR equalizer filters may operate on the output r'_n of the Ungerboeck Observation Model, on the output r_n of the Forney observation model, or on the outputs of a filter matched to the undistorted pulse shape $p_c(t)$. To simplify the discussion in this entry, filter-based equalizers operating with the Forney Observation Model are the only ones described.

Linear Equalizers

The linear equalizer is an FIR filter operating on the outputs r_n of the Forney Observation Model. The arrangement is illustrated in Fig. 5 where $C(z)$ is the z -transform of the FIR equalizer filter. The output of the equalizer filter $\tilde{a}_n$ is the input to a symbol-by-symbol (SxS) detector to compute the symbol estimate $\hat{a}_n$.

The probability of error is the probability that $\hat{a}_n \neq a_n$.

The FIR equalizer filter is defined by the filter coefficients

$$c_{-L_1} \quad \cdots \quad c_0 \quad \cdots \quad c_{L_2} \quad (16)$$

whose corresponding z -transform is

$$C(z) = \sum_{n=-L_1}^{L_2} c_n z^{-n}. \quad (17)$$

This formulation is general in the sense that a purely causal FIR filter is the special case $L_1 = 0$ and a symmetric filter is the special case $L_1 = L_2$. Starting with Eq. (13), the equalizer filter output is

$$\tilde{a}_n = \sum_{i=-L_1}^{L_2+L} q_i a_{n-i} + \sum_{i=-L_1}^{L_2} c_i w_{n-i} \quad (18)$$

where q_i is the impulse response of the cascade of the channel filter and the equalizer filter:

$$q_i = \sum_{j=-L_1}^{L_2} c_j f_{i-j}, \quad -L_1 \leq i \leq L_2 + L. \quad (19)$$

The equalizer output may be expressed as

$$\tilde{a}_n = q_0 a_n + \sum_{\substack{i=-L_1 \\ i \neq 0}}^{L_2+L} q_i a_{n-i} + \sum_{i=-L_1}^{L_2} c_i w_{n-i}. \quad (20)$$

The first term on the right-hand-side of Eq. (20) is a scaled version of a_n and is the desired input to the SxS detector. If this were the only term in Eq. (20) and $q_0 = 1$, then the SxS detector would never make an error. The second term on the right-hand-side of Eq. (20) is the intersymbol-interference (ISI) present in the equalizer filter output. The goal of any good equalizer filter is make this term as small as possible. The third term on the right-hand-side of Eq. (20) is the contribution of the additive noise to the equalizer filter output. There are two popular criteria by which the equalizer filter coefficients are defined: The zero-forcing (ZF) criterion and the minimum mean-squared error (MMSE) criterion. The differences between them are how they incorporate the second and third terms on the right-hand-side of Eq. (20).

The ZF equalizer selects the filter coefficients to minimize the ISI term in Eq. (20). The original formulation of the problem (Lucky 1965) was based on the absolute value of the ISI:

Equalization Techniques for Single-Carrier Modulations, Fig. 5

The relationship between the FIR equalizer filter, represented by its z -transform $C(z)$, and the Forney Observation Model

$$\left| \sum_{\substack{i=-L_1 \\ i \neq 0}}^{L_2+L} q_i a_{n-i} \right| \leq A \left| \sum_{\substack{i=-L_1 \\ i \neq 0}}^{L_2+L} q_i \right| \leq A \sum_{\substack{i=-L_1 \\ i \neq 0}}^{L_2+L} |q_i| \quad (21)$$

where $A = \max_n \{a_n\}$. The object function to be minimized is

$$\sum_{\substack{i=-L_1 \\ i \neq 0}}^{L_2+L} |q_i| \quad (22)$$

which is called the maximum (or peak) distortion (Lucky 1965). For an infinitely long equalizer filter ($L_1 = L_2 = \infty$), the equalizer filter coefficients may be selected to produce $q_n = \delta_n$. For an FIR equalizer filter ($L_1 < \infty$, $L_2 < \infty$), the minimization produces $q_n = 0$ only for $-L_1 \leq n \leq L_2 + L$. This means the second term in Eq. (20) is not entirely eliminated. A second approach uses as the object function the least squares criterion (Hayes 1996).

$$|q_n - \delta_{n-n_0}|^2. \quad (23)$$

Choosing the equalizer filter coefficients to minimize (23) produces, for the equalizer filter, a filter that is the best least squares approximation to the inverse filter.

The shortcoming of the ZF equalizer is that the design criteria neglects the noise term in Eq. (20). The impact of this neglect is most dramatic when equalizing a channel whose discrete-time Fourier transform (DTFT) $|H(e^{j\omega})|$ displays one or more nulls. (The term “null” is used loosely here to mean not only the property that $|H(e^{j\omega})| = 0$ but also $|H(e^{j\omega})|$ is very small, say less than 0.1 times the maximum values of $|H(e^{j\omega})|$.) The DTFT of the ZF equalizer $C(e^{j\omega})$ is the inverse or approximate inverse of $H(e^{j\omega})$, i.e., $H(e^{j\omega})C(e^{j\omega}) \approx 1$. The action of $C(e^{j\omega})$ “equalizing” the amplitude variations in $H(e^{j\omega})$ is the source of the name “equalizer.” For channels with nulls, the

equalizer multiplies the spectral components corresponding to the channel nulls by large values. But the noise components corresponding to the frequencies of the nulls are also multiplied by the large values. The result is a noise term in Eq. (20) with very high variance. This property is often called “noise enhancement” and represents one of the challenging trade-offs with linear equalizers: ISI is reduced at the expense of reduced signal-to-noise ratio.

One way to address the shortcoming to the ZF equalizer is to adopt the mean-squared error criterion (Widrow 1966).

$$E \left\{ |a_n - \tilde{a}_n|^2 \right\}. \quad (24)$$

The solution for the equalizer filter coefficients is a form of the Wiener-Hopf equations and the resulting equalizer is known as the minimum mean-squared error (MMSE) equalizer. Because the mean-squared error criterion includes both the ISI and the noise terms in Eq. (20), the MMSE equalizer is able to balance the contributions of both ISI and noise enhancement in the solution. The result is less noise enhancement, but noise enhancement can still be a problem. In the limit as $N_0 \rightarrow 0$, the MMSE equalizer converges to the ZF equalizer.

The length of the ZF or MMSE equalizer $L_1 + L_2 + 1$ is an important consideration. The computational complexity increases with equalizer length, and this recommends using an equalizer as short as possible. In opposition, the ability of the equalizer to remove ISI increases with length, and this recommends using an equalizer as long as possible. Whereas increasing equalizer length improves performance, it is usually the case that increasing the equalizer length beyond a certain value returns diminishing improvements in performance. What this length is depends on the characteristics of the channel: its length L and the degree of amplitude variation with frequency. Experiments in Treichler et al. (1996) recommend an equalizer length 3–5 times L . But, short channels with deep spectral nulls require an equalizer much longer than this.

Equalization Techniques for Single-Carrier Modulations, Fig. 6 A block diagram of the decision-feedback equalizer based on the Forney Observation Model

E

Nonlinear Equalizers: The Decision-Feedback Equalizer

Both the ZF and MMSE equalizers suffer from a reduction in signal-to-noise ratio due to noise enhancement when the channel exhibits spectral nulls. In such circumstance, a nonlinear equalizer, known as the decision-feedback (DF) equalizer, exhibits better performance (Austin 1967).

The DF equalizer comprises two FIR filters arranged as shown in Fig. 6. The first filter is called the feedforward filter and is defined by the coefficients $c_{-L_1}, \dots, c_0$ with z -transform

$$C(z) = \sum_{n=-L_1}^0 c_n z^{-n}. \quad (25)$$

The second filter is called the feedback filter and is defined by the coefficients $d_1, \dots, d_{L_2}$ with z -transform

$$D(z) = \sum_{n=1}^{L_2} d_n z^{-n}. \quad (26)$$

This formulation follows the well-established convention of designating the feedforward filter as an anticausal filter and the feedback filter as a causal filter. The input to the SxS detector is

$$\tilde{a}_n = \sum_{i=-L_1}^0 c_i r_{n-i} + \sum_{j=1}^{L_2} d_j \hat{a}_{n-j}. \quad (27)$$

The first term on the right-hand-side of Eq. (27) represents the action of the feedforward filter that reduces, but does not eliminate, the ISI in r_n .

The second term on the right-hand-side of Eq. (27) reproduces the ISI remaining in the output of the feedforward filter and subtracts it from the output of the feedforward filter in the hopes of producing an ISI-free input to the SxS detector. Noise enhancement is greatly reduced because the feedback filter operates on symbol decisions which, if they are correct, are noise free. Either the ZF or MMSE criterion may be used to compute the coefficients of the feedforward filter. The MMSE is the most common. The feedback filter coefficients are set to the negatives of the causal part of $q_n = f_n * c_n$.

Choosing the equalizer length is a two-step process. The performance vs. length trade-off for feedforward equalizer follows that of the MMSE equalizer described above. The length of the feedback equalizer filter needs to be at most L .

Frequency-Domain Equalizers

Some channels require very long equalizers to achieve satisfactory performance; frequency-domain equalizers address the computational burden by leveraging the computational advantages of the FFT algorithm. The filtering operation required by the linear equalizer is accomplished by performing point-by-point multiplications of the discrete-Fourier transforms (DFT) of the received signal samples and the equalizer filter.

The frequency-domain equalizer was first described in Walzman and Schwartz (1973). A block diagram illustrating the idea is shown in Fig. 7. The k -th element of the length- K FFT of the received sequence r_n is

Equalization Techniques for Single-Carrier Modulations, Fig. 7 A block diagram illustrating the frequency-domain equalizer based on the Forney Observation Model

$$R_k = \sum_{n=0}^{K-1} r_n e^{-j2\pi nk/K}, \quad k = 0, \dots, K-1. \quad (28)$$

The relationship between the f_n and F_k is identical. Equalization is accomplished in the frequency domain by performing a point-by-point multiplication of R_k and the equalizer C_k . An inverse-FFT is applied to the product to return to the sample domain. The frequency-domain equalizer may be

$$C_k = \begin{cases} \frac{1}{F_k} & \text{ZF equalizer} \\ \frac{F_k^*}{|F_k|^2 + 2N_0/E_s} & \text{MMSE equalizer,} \end{cases} \quad k = 0, \dots, K-1. \quad (29)$$

Point-by-point multiplication in the DFT domain is equivalent to circular convolution/deconvolution in the sample domain. But the ISI occurs through linear convolution in continuous-time domain, cf. Figure 1. To match the two, a *cyclic prefix* is used at the transmitter to convert linear convolution to circular convolution in preparation for frequency-domain equalization.

The operations representing the computations of the channel F_k and the equalizer C_k are shown in dashed lines in Fig. 7. This is because for static channels, the FFT to produce F_k and the computations to produce C_k need to be performed only once, or infrequently in the case of slowly varying channels.

Summary

In summary, linear equalizers, based on equalizer filters optimizing the ZF or MMSE criteria, are low-complexity alternatives to the maximum likelihood sequence estimator. These equalizers comprise simple FIR filters followed by a symbol-by-symbol detector. For a channel with one or more spectral nulls, noise is the limiting factor in equalizer performance. Noise enhancement is reduced by using a decision-feedback equalizer. For long channels (large L), the length of the equalizer filter required to achieve acceptable performance can be prohibitively large. In this case, frequency domain equalization techniques can be used. Frequency-domain techniques require the insertion of a cyclic prefix to convert linear convolution into circular convolution and can be limited by noise enhancement.

Adaptive Equalizers

The equalizers described in the previous two sections relied on knowledge of the equivalent discrete-time channel relating the transmitted symbols to the received samples. In practice, this knowledge is obtained by estimating the equivalent discrete-time channel from the received samples corresponding to a known sequence symbol inserted into the data stream by the transmitter. The equalizer filter coefficients are computed from the channel estimate as the solution to matrix/vector equations. The

dimensions of the matrix and vector are determined by the equalizer length. For long equalizers, computing the solution can be prohibitively complex.

The alternative is to use an adaptive filter (Haykin 2013). Equalizers based on adaptive filters are called adaptive or automatic equalizers. The structure of the adaptive ZF and MMSE equalizers is identical to that shown in Fig. 5 except $C(z)$ is replaced by an adaptive filter. The structure of the adaptive DF equalizer is identical to that shown in Fig. 6 except $C(z)$ and $D(z)$ are replaced by adaptive filters.

An adaptive filter is one where the filter coefficients are recursively updated based on the error signal $e_n = a_n - \tilde{a}_n$. The LMS algorithm for the ZF filter coefficient updates (Haykin 2013) is

$$\begin{bmatrix} c_{-L_1} \\ \vdots \\ c_0 \\ \vdots \\ c_{L_2} \end{bmatrix}_{n+1} = \begin{bmatrix} c_{-L_1} \\ \vdots \\ c_0 \\ \vdots \\ c_{L_2} \end{bmatrix}_n + \mu e_n \begin{bmatrix} a_{n+L_1}^* \\ \vdots \\ a_n^* \\ \vdots \\ a_{n-L_2}^* \end{bmatrix} \quad (30)$$

where the subscript on the vector of equalizer filter coefficients indicates the time index that the filter coefficients are used. The recursion converges to the correct solution if the step size $\mu > 0$ is sufficiently small. The LMS algorithm for the MMSE equalizer filter coefficient updates is

$$\begin{bmatrix} c_{-L_1} \\ \vdots \\ c_0 \\ \vdots \\ c_{L_2} \end{bmatrix}_{n+1} = \begin{bmatrix} c_{-L_1} \\ \vdots \\ c_0 \\ \vdots \\ c_{L_2} \end{bmatrix}_n + \mu e_n \begin{bmatrix} r_{n+L_1}^* \\ \vdots \\ r_n^* \\ \vdots \\ r_{n-L_2}^* \end{bmatrix} \quad (31)$$

and the LMS algorithm for the DF equalizer filter coefficients is

$$\begin{bmatrix} c_{-L_1} \\ \vdots \\ c_0 \\ \vdots \\ c_{L_2} \end{bmatrix}_{n+1} = \begin{bmatrix} c_{-L_1} \\ \vdots \\ c_0 \\ \vdots \\ c_{L_2} \end{bmatrix}_n + \mu e_n \begin{bmatrix} r_{n+L_1}^* \\ \vdots \\ r_n^* \\ \vdots \\ a_{n-L_2}^* \end{bmatrix} \quad (32)$$

Recursions for the MMSE frequency domain equalizer filter coefficients C_k are described in Walzman and Schwartz (1973).

The advantages of the ZF, MMSE, and DF adaptive equalizers is that they do not have to “know” the channel f_n and do not have to compute the solutions to a potentially high-dimensional matrix vector equation. But, adaptive equalizers do need to be “trained”: a sufficiently long sequence of known symbols, often called a “training sequence,” is used as the known symbols in Eqs. (30), (31), and (32). The length of the training sequence must be on the order of the convergence time of the equalizer. The convergence time is determined by the step size μ and by the deterministic autocorrelation function of the channel f_n . Once the adaptive filter has converged, operation may shift to a decision directed mode where a_i is replaced by $\hat{a}_i$ in Eqs. (30), (31), and (32). This decision-directed mode allows the adaptive filter to track small, slow changes in the channel.

Convergence time can be reduced by using a more sophisticated recursion, such as the recursive least squares (RLS) algorithm Haykin (2013). Improved convergence time is achieved at the expense of increased computational complexity required by the recursive updates.

Blind Equalizers

Blind equalizers are based on adaptive filters that do not need to be trained. The adaptive filters use LMS-type updates based on a well-chosen non-linear property of the data symbols. The adaptive filter is able to converge to an equalizer filter that

Equalization Techniques for Single-Carrier Modulations, Fig. 8

Block diagrams of the system used to describe blind equalizers: (a) the continuous-time system of Fig. 1 using a receive filter with impulse response $f_c(t)$ whose output is sampled at T_s -spaced intervals; (b) the equivalent discrete-time system of corresponding to (a) together with the adaptive filter that forms the blind equalizer

gives good performance even without knowledge of the channel or the data symbols.

Blind equalizers are used in situations where the channel is unknown. Consequently, the Forney Observation Model (which requires knowledge of the channel) does not apply here. In its place, we consider the systems illustrated in Fig. 8. The block diagram in Fig. 8a starts with the system in Fig. 1 and adds a continuous-time receiver filter with impulse response $f_c(t)$. The receiver filter may be an ideal low-pass filter or a filter matched to the pulse shape. The output of the receiver filter is sampled at T_s -spaced intervals to produce the sequence x_n . The system in Fig. 8b illustrates the equivalent discrete-time system corresponding to Fig. 8a and the position of the adaptive filter that forms the blind equalizer. The equivalent discrete-time system comprises a filter with samples $h'_n \triangleq h'_c(nT_s)$ where

$$h'_c(t) = p_c(t) * h_c(t) * f_c(t). \quad (33)$$

The noise samples v'_n are samples of the output of receive filter due to $z_c(t)$ and comprise a complex-valued wide-sense stationary circularly symmetric discrete-time normal random process with autocorrelation function is formed from T_s -spaced samples of the temporal autocorrelation

function of the receive filter. The output of the adaptive filter forms the input to the SxS detector.

The equalizer filter coefficients are given by Eq. (16) and the update is of the form

$$\begin{bmatrix} c_{-L_1} \\ \vdots \\ c_0 \\ \vdots \\ c_{L_2} \end{bmatrix}_{n+1} = \begin{bmatrix} c_{-L_1} \\ \vdots \\ c_0 \\ \vdots \\ c_{L_2} \end{bmatrix}_n - \mu \nabla_n J \quad (34)$$

where $\nabla_n J$ is the gradient vector of a scalar valued object function J with respect to the equalizer filter coefficients at time step n . This is the gradient descent method for minimization: the filter coefficient vector at time step $(n+1)$ moves in the opposite direction of the gradient of the object function evaluated at the coefficient vector at time step n . The step size is controlled by the scalar $\mu > 0$.

The two most-studied object functions are the generalized Sato function (Benveniste and Goursat 1984):

$$J = \frac{1}{2} E \left\{ |\tilde{a}_n - \gamma \operatorname{csgn}(\tilde{a}_n)|^2 \right\} \quad (35)$$

where $\gamma = E\{|a_n|^2\}/E\{|a_n|\}$ and

$$\text{csgn}(\tilde{a}_n) = \text{sign}(\text{Re}\{\tilde{a}_n\}) + j \text{sign}(\text{Im}\{\tilde{a}_n\}), \quad (36)$$

and Godard's constant modulus function Godard (1980)

$$J = \frac{1}{2} \text{E} \left\{ \left[|\tilde{a}_n|^2 - R_2 \right]^2 \right\} \quad (37)$$

where $R_2 = \text{E}\{|a_n|^4\}/\text{E}\{|a_n|^2\}$. Of the two, Godard's constant modulus function is the most widely used.

The blind equalizer based on Eq. (37) uses an adaptive filter with the updates of the form Eq. (34) with J given by Eq. (37). Computing the gradient ∇J and using a single point estimate of the expectation in Eq. (37), the adaptive filter update is

$$\begin{aligned} \begin{bmatrix} c_{-L_1} \\ \vdots \\ c_0 \\ \vdots \\ c_{L_2} \end{bmatrix}_{n+1} &= \begin{bmatrix} c_{-L_1} \\ \vdots \\ c_0 \\ \vdots \\ c_{L_2} \end{bmatrix}_n \\ &+ \mu \tilde{a}_n \left(|\tilde{a}_n|^2 - R_2 \right) \begin{bmatrix} x_{n+L_1}^* \\ \vdots \\ x_n^* \\ \vdots \\ x_{n-L_2}^* \end{bmatrix} \end{aligned} \quad (38)$$

This blind equalizer update algorithm is known as the constant modulus algorithm.

Summary

Equalization is used to enable the detection of data symbols in the presence of ISI caused by nonideal propagation channels. The ML solution comprises a sequence estimator usually implemented by the Viterbi algorithm operating on a trellis where the number of states grows exponentially with channel length. For long channels, the computational complexity of the ML estimator is prohibitive, so low-complexity filter-based

equalizers are used. Linear equalizers are based on an FIR filter and a symbol-by-symbol detector. The computational complexity of the equalizer is modest (except for the need to compute the equalizer filter coefficients from the known or estimated channel), but performance suffers from noise enhancement. The decision-feedback equalizer reduces the noise enhancement problem. The computational complexity of implementing long equalizer filters can be reduced by performing equalization in the DFT domain. Because DFT-domain multiplication corresponds to circular convolution, a cyclic prefix must be inserted at the transmitter to convert linear convolution to circular convolution. The computational complexity of computing the equalizer filter coefficients can be reduced by using adaptive filters: the equalizer filters converge to the true equalizer filter when operating on the samples corresponding to a sequence of known training symbols. Adaptive versions of the zero-forcing, MMSE, and decision-feedback equalizers are straightforward to implement. The need for training symbols can be eliminated using blind equalizers.

EV Charging Scheduling

Definitions

Determine when the electric vehicles (EVs) should visit which charging station during the trip to achieve certain objectives, e.g., minimizing the waiting time or charging cost, maximizing the profit of charging network, load balancing of the electricity grid, and so on.

Historical Background

Charging scheduling plays an important role in enabling the intelligent transportation system with EVs. Unlike vehicles powered by gas or diesel, EVs are powered by electricity from in-car energy storage such as batteries or a fuel cell. Due to the limited capacity of in-car energy storage, EVs need to be charged more frequently than conventional cars. Frequent charging not only takes time (including the time to reach a charging station and that to complete charging) but also reduces the battery lifetime. Besides, electricity price varies in time and locations. An EV driver might choose to charge at private charging facilities such as home or office parking lot. There is also a need to charging at public charging stations, particularly for long trip and heavy-duty cars. Compared to the former case, a public charging station may be occupied by many drivers during a certain period, leading to long waiting time for charging. Hence, the charging decision of individual EV needs to be properly planned for the best driving experience and efficient utilization of electricity.

EV charging scheduling shares the common goal as route planning (Eisner et al. 2011), a function already available in many personal navigation devices. Both attempt to assist the EV drivers to reduce their traveling time. In essential, route planning finds the optimal end-to-end path for the individual driver based on some given information, such as departure and destination location, route preference, and so on. Charging scheduling guides the driver on when and where to charge during the trip. To this end, real-time status about the availability of charging stations and instantaneous traffic conditions must be taken into account in charging scheduling. While route planning can also respond to the traffic conditions, it is performed to minimize the traveling time of individual vehicles. Differently, charging scheduling is made considering the entire vehicular networks and can be used to adjust the load of electricity grid. As a result, charging scheduling has a broader impact to the entire transportation network and electricity power system.

In general, effective charging scheduling for EVs is difficult. For some scenarios, such as auto shipping and public transportation, the route can be known in a priori, but this may not be the case for personal travels or daily commuting that involve rapid changes on road conditions and per-driver preference. The random movement of EVs also causes uncertainties in both time and space. Additionally, the status of charging stations, such as availability and waiting lines, varies at different times and locations.

To support charging scheduling, real-time and reliable bidirectional communications between EVs and the control center that derives charging scheduling based on the collected information from EVs are of paramount importance. Considering the large number of EVs in the future, massive connectivity with high mobility is expected that challenges the existing wireless networks such as mobile cellular networks and wireless local area networks (WLAN) as both are not designed to serve EV-related communications. In the USA, the technology called dedicated short-range communications (DSRC) (Kenney 2011) or known as wireless access in vehicular environments (WAVE) has been standardized to support vehicular-to-vehicular (V2V) and vehicular-to-roadside (V2R) communications. However, existing DSRC has a bandwidth of 10 MHz per channel only and the achievable data rate up to 27 Mbps. On the other hand, fourth-generation cellular network or known as Long-Term Evolution (LTE) has a wider bandwidth and much higher data rate. Despite 4G-LTE will be enhanced in its future release to support massive connectivity with ultralow latency, it operates in the licensed band leading to a higher operational cost than DSRC. The debate over DSRC versus LTE remains open at both the regulation and commercialization level.

Apart from the underlying communication networks, efficient algorithms for EV charging scheduling serve as the key enabler for connected EVs. Wang et al. (2016a) provide a comprehensive survey on EV charging scheduling. Existing EV charging scheduling can be further classified

in two categories depending on the energy source of the charging stations. In the first category, charging stations are hooked up to the electrical grid, e.g., Tesla Supercharger stations (Tesla Motors 2017). Since the electrical grid is designed to be always on, EVs can be charged immediately at an available charging station. In this context, the EV charging scheduling can be designed, for example, to navigate EVs to the charging station that minimizes the time cost for charging, including the travel time to the charging station, the waiting time for an available outlet in the charging station, and the actual charging time, as studied by Wei et al. (2015). Meanwhile, the residual electricity of the EV needs to be taken into account when determining the route to an appropriate charging station. Such a problem has been shown by Zhu et al. (2014) as an NP-complete problem, and thus heuristic or approximated algorithms must be developed to quickly derive the scheduling results. To make electricity utilization more efficient, EVs may not only draw energy from the grid but also feed energy back to the grid, resulting in a more sophisticated design for two-way charging scheduling. As revealed by Zeng et al. (2013), two-way charging scheduling can increase the utilization of charging stations, reduce the charging delay, and improve the peak-to-average ratio of electric load.

The second category of EV charging scheduling considers off-grid charging stations that rely on renewable energy such as solar and wind. As a clean energy source, renewable energy produces much less pollution to the environment and thus promises a sustainable transportation system. There have been some initiatives being taken, e.g., Driving on Sunshine program (Charge Across Town 2018) in the San Francisco bay area and California, that demonstrate the great potential of off-grid charging stations. However, renewable energy is intermittent and unpredictable in its arrival pattern that challenges EV charging scheduling. In addition, renewable energy alone may not offer enough energy to fulfill the charging need in the public area. An alternative is thus to jointly use grid

power and renewable energy at the charging stations. In this case, EV charging scheduling needs to adapt to the intermittence of the renewable energy, the uncertain vehicle arrivals, and the variation of the grid power price. Such a problem can be formulated as a stochastic optimization problem under the framework of Markov decision process (MDP) (Zhang et al. 2014). The similar problem aiming to reduce the charging time is also studied by Wang et al. (2016b), which develops a two-stage EV charging mechanism to determine the optimal energy generation and charging rate of each EV.

Key Applications

Charging scheduling is essential to intelligent transportation system with EVs. Drivers use the scheduling information provided by a control center to decide when and where to charge during the trip in order to save traveling time and cost. The charging scheduling policy can incorporate the electricity price and load of charging stations so as to maximize the efficiency of entire charging network or the profit of charging service providers. The electricity grid can also leverage charging scheduling for load balancing and possibly optimizing the integration of renewable energy into the power system.

The role of cellular technologies in enabling ad hoc vehicular networks.

Introduction

The actual trends in wireless networking are (i) to extend services offered by traditional providers with unlimited peer-to-peer capabilities and (ii) to dynamically integrate available communications segments to exploit all communication opportunities. The latter feature is inherently dictated by the correlations among data flows which in turn are due to wide sense *social* relationship, i.e., the requirements arising when establishing a *group* of devices.

A challenging domain for the integration and evolution of heterogeneous information and communication technologies (ICTs) is represented by the automotive industry. Indeed, in order to provide drivers with a more pleasant and safer driving experience, vehicles are gradually endowed with sensing, actuation, computing, user interaction, and communications capabilities, thus becoming *intelligent nodes* capable of interconnecting, cooperating, and even autonomously adapting to the surrounding environment. Since drivers usually spend a non-negligible fraction of time in vehicles and their behaviour may have a strong impact at a collective scale (e.g., pollution and noise in a city), the adoption of advanced ICT approaches for achieving a more safe, green, and effective mobility management is still an open research issue (Gerla and Kleinrock 2011).

The familiarity with the *social networking* paradigm makes people used to share information online with (in)direct *contacts* and use it in their everyday life depending on the degree of trust. Moreover, the widespread adoption of existing social-based traffic and navigation applications paves the way for introducing novel vehicular services and applications that are typically location-based as well as community driven. To this purpose, wireless communications

may enable the effective exchange of *mobile* information among vehicles in a participatory way to enhance open information sharing and knowledge exchange processes. Despite 3G systems have been capable to support *generic* and *individual* terminal mobility, recently, investigation activities have been started on the possible use of 4G Long Term Evolution (LTE) standard to ensure connectivity between vehicles, roadside infrastructure, and the people inside and around the so-called connected car (3rd Generation Partnership Project – Technical Specification Group Services and System Aspects 2015). The definition of a generic interface, namely, V2X, between a vehicle and a generic device has been addressed, generalizing the existing communication interfaces as V2V (between vehicles), V2P (between a vehicle and a device carried by a generic individual), and V2I (between a vehicle and a roadside unit (RSU)). With reference to this aspect, device-to-device (D2D) communications are gaining momentum in wireless systems evolution: in 4G standard this concept has been introduced to enhance the coverage via proximity services (ProSe) provisioning or to effectively cope with machine-type communications (MTCs), while in 5G D2D is expected to play a crucial role involving also networking aspects (Malandrino et al. 2014; Shen 2015).

In addition, several use cases have been investigated spanning from emergency, collision, and queue warnings to adaptive cruise control and automated parking. All these services require advanced multicast scheme management, able to jointly support data gathering, fusion, and dissemination within or among (virtual) areas. This involves the clustering of *correlated* vehicle groups according to a hierarchical topology inspired by the *small-world* networking approach and an optimal ad hoc resource allocation policy.

In this entry, we introduce a novel perspective, where a generalized ad hoc paradigm is introduced in cellular networks according to 5G vision to enhance vehicular social networks with the support of both infrastructure and crowd sourcing-based networking while mitigating cost and complexity and increasing scalability,

robustness, and resilience. First, the context-aware vehicular social network paradigm is introduced focusing on their main features and challenges, as well as on opportunities offered by context-aware adaptation. We also discuss how D2D communication schemes could empower social-aware applications in vehicular communications, with specific focus on two use cases (i.e., safety and early warning applications or autonomic transportation systems for *smart cities*). Further, we provide an insight on wireless communication technologies enabling this paradigm shift, with a special regard to beyond 4G systems, mainly LTE-V concept.

Overview on Vehicular Social Networks

Vehicular social networks (VSNs) are an emerging type of social network which allows the exchange of information among drivers, passengers, and vehicles by leveraging dynamic relationships typically built according to vehicles' physical proximity as well as common interests and context (i.e., similar destination) (Yang and Wang 2015).

The joint exploitation of social relationships with emerging communication technologies is considered a promising approach for dramatically improving the added value provided by applications in vehicular networks (e.g., navigation safety applications, navigation efficiency, entertainment, participatory, and urban sensing, emergency (Gerla and Kleinrock 2011)). For instance, ongoing standardization activities on LTE-based V2X communication are specifically focused on supporting the delivery of intelligent services enabled by cooperative awareness (3rd Generation Partnership Project – Technical Specification Group Services and System Aspects 2015). Indeed, considering the social dimension in vehicular networking can bring several advantages. First, since each vehicle can be considered a producer of information, the information exchanged in a VSN may surpass in quality, timing, and local coverage, the one

provided by online remote services. Second, the availability of information on users' common interests and preferences can be exploited to improve the dissemination of information, for instance, by minimizing information delivery to uninterested parties. VSNs can also facilitate the exchange of information, media content, and recommendations for activities related to mobility (e.g., entertainment inside the vehicles for passengers and tourism).

Nonetheless, collaboration in a VSN is not merely limited to application information exchange. Each node (the vehicle itself through the Onboard Unit, OBU, or any other smart device in the vehicle environment which may represent the vehicle or the user digital identity, such as smartphones) conveys sensors, actuators, processing, and communication resources that can contribute to the creation and maintenance of communities targeting the delivery of communication services (opportunistic *networking*) and/or information processing and dissemination services (opportunistic *computing*). Indeed, opportunistic contacts can be exploited to support multi-hop communication schemes (e.g., with or without the assistance of the network infrastructure), thus allowing data exchange between indirect contacts. Moreover, opportunistic networking can ease the cooperation among devices in order to execute processing and information dissemination tasks, by sharing computing, storage, and communication resources for the accomplishment of a given task. On this perspective, VSNs can be progressively configured as a *technological ecosystem* with increasingly autonomous features, which leverage infrastructure resources (e.g., wireless and wired communication infrastructure, remote information services and resources) when needed.

This vision is currently being strengthened by the ongoing evolution of cellular communications toward 5G. Indeed, 5G infrastructure is envisioned as a *neural bearer* where *everything* (applications, processing resources, network, data, etc.) can be provided as a service, and most of intelligence, including context-aware adaptation logic, will be distributed at the edge,

i.e., in the aggregation and access segments up to the end user premises (Soldani and Manzalini 2015). Virtualization technologies are considered key technologies for achieving this objective, with the introduction of cloud platforms at the edge, close to end users, to support the evolution toward cloud-based radio access as well as a novel application delivery approach, targeting faster service delivery and augmented reality (ETSI 2015). Therefore, information processing tasks could be performed locally (on the vehicle and in a proximity-based group of vehicles), at the edge (access/aggregation network), as well as remotely (network operators and service providers' data centers).

As an example, the roadside infrastructure (e.g., the LTE base station site) could host the virtual infrastructure resources for running an application that processes sensor data produced by approaching vehicles, elaborates them, and derives relevant information to be delivered to interested parties with low latency while also delivering data to remote cloud services for resource-demanding processing tasks, such as big data analytics. For instance, a sudden deceleration of a group of vehicles on a road segment could be detected at the roadside infrastructure through collection and real-time analysis of vehicles' speed and location information and trigger the timely delivery of an alert message to incoming vehicles (e.g., possible congestion or obstacle on the road).

In addition to infrastructure-assisted schemes for information processing and dissemination, routing, and communication resource management, also non-infrastructure-assisted schemes can be conceived. Moreover, on top of an opportunistic V2V network, resources hosted by nodes could be exposed as a service and dynamically composed across different nodes for providing added-value application services to the members of the community. For instance, a video captured by a camera on one or more vehicles could be processed by a video transcoder provided by a smartphone, analyzed by an application running on a vehicle OBU, and the results disseminated to the other peers of the network. Figure 1 shows two examples of cooperation at both the appli-

cation and networking layers, enabled by social awareness, as discussed above, where V2X communication is a key enabling technology.

With respect to online and mobile social networks, VSNs pose several specific challenges, mainly due to the fact that the topology of a VSN very often changes and it is formed by peers that move at high speed, then their contact is time limited in the order of tens of seconds, and the technological infrastructure is made by heterogeneous components (Mezghani et al. 2014). In such context, computing trust and guaranteeing trustworthy information sharing in VSNs are challenging requirements (Yang and Wang 2015). Moreover, efficient techniques for handling the dynamic changes in the community structure (i.e., vehicles joining and leaving the community) as well as social-aware routing and communication strategies for the effectively and efficiently disseminating information in a vehicular social network are needed (Maaroufi and Pierre 2014).

Application Scenarios and Communications Use Cases

Cooperation among vehicles can enable a wide range of application services for the benefit of several categories of end users: drivers of private vehicles, drivers of public or collective transport vehicles, transportation authorities, and public administrations, to name a few. Hereafter we provide some scenarios to illustrate how social- and context-aware applications can be empowered by multi-hop D2D communication. To this purpose, we preliminary focus on three different networking use cases, starting from (i) critical information diffusion performed by a single vehicle toward a potential group of neighbors (*anycastransmission*) up to (ii) data exchange among convoys when a communication opportunity arises (*intergroup communication*) and (iii) data aggregation and fusion performed by a vehicle acting as gateway to the Internet (*data gathering and fusion*), as depicted in Fig. 2. As soon as communications become less sporadic and context aware, an ad hoc networking scheme is required: in particular we indicated (i) a basic

Evolution of Vehicular Networks in the Transition from 3G to 4G Systems, Fig. 1 Examples of cooperation at the application and networking layer in vehicular networks

flooding scheme or more advanced solutions relying on (ii) disruption-tolerant networking (DTN) or classical mobile ad hoc networking (MANET).

Hereafter we discuss how these networking schemes may support communication requirements of social-aware vehicular applications for safety and early warning and autonomic transport in smart cities.

Safety and Early Warning Applications

Safety and early warning applications are one of the most investigated types of applications in vehicular systems. Basing on the dynamic exchange of context information among OBUs and RSUs, dynamic communities can be built by grouping vehicles that are in the same geographical area and have in common a significant part of

their path or the final destination. For example, events of interest are an abrupt deceleration of (group of) vehicles, an obstacle on the road, a sudden change of weather conditions, and a breakdown of a vehicle. This information can be provided by drivers or passengers (as already enabled by existing applications, e.g., Waze) or detected and automatically *posted* by vehicles so to speed up the time needed for generating and disseminating the alert.

In the data gathering and fusion case, a vehicle, elected as *coordinator* of a group of vehicles, collects context information provided by group members and executes a task for analyzing this information and infers the occurrence of events of interests. For instance, a sudden deceleration and change of direction by a few vehicles may be interpreted as an obstacle on the roadway and

Evolution of Vehicular Networks in the Transition from 3G to 4G Systems, Fig. 2 Potential use cases from a data exchanging and networking perspective

dispatched to other interested peers via an anycast transmission scheme.

Autonomic Transport Systems in Smart Cities

The paradigm of *opportunistic* communication is one of the main ICT enablers in the fields of smart cities. Indeed, adaptive and resilient communications are expected to play a key role in the achievement of smart city goals (i.e., sustainable economic growth, quality of life, rational use of resources through the active involvement and participation of citizens). In particular, V2X communications can enable novel scenarios of cooperation among people, vehicles, and urban infrastructure (e.g., traffic lights, streetlights, message boards, etc.) in order to achieve the best trade-off between private interests (e.g., minimize travel time to work) and public goals (e.g., reduce CO₂ and noise levels). People, vehicles, and smart urban

objects can act as sensors and exchange context information. Distributed or centralized decision approaches can be implemented that based on this information can dynamically adapt the use of urban resources (e.g., change traffic light policies, allow or avoid access to a road). As an example, priority at a crossing road could be dynamically decided according to current situation: e.g., number of vehicles on a lane, a congestion after the crossroad, an approaching ambulance, etc. Drivers can be appropriately alerted through road messages and in vehicle alerts. Furthermore, with the introduction of autonomous vehicle control systems, vehicles could cooperatively agree on a traffic flow policy and autonomously enforce the decision by intergroup communicating (e.g., two groups of vehicles approaching a road intersection on different directions agree on the priority and accordingly decelerate or accelerate).

Enabling Communication Technologies

Wireless communications are still experiencing an impressive evolutionary trend, enabling users to independently collect and share information through *heterogeneous* devices and networks. According to the innovative vision driving the transition to the so-called 5G systems, the simultaneous availability of multi-radio technologies could be advantageously exploited by means of integration and joint management. This increases the networking opportunities leading to a *social* inspired connectivity paradigm. An interesting case study is represented by the so-called vehicular ad hoc networks (VANETs), which aim at revolutionizing the traveling experience especially within a smart city (Rasheed et al. 2013). The underlying concept is indeed to provide each vehicle with a *wireless identity* which is not simply a *global* identifier, as it happens in IPv6, but it is strictly related with user profiles (drivers and passengers) and the context as well. This allows to increase the interoperability and to *extend the horizon* with benefits in terms of safety, quality of experience, and resource optimization. However, this vision strictly depends upon the presence of a communications infrastructure providing connectivity to all the vehicles. In the following we briefly overview the candidate technologies (Karagiannis et al. 2011), spanning from available approaches toward an enhanced paradigm of ad hoc interaction that relies upon next-generation networks.

VANET Architectures

DSRC-WAVE

The available technology for supporting the intelligent transportation system (ITS) applications in the short-range communications is represented by wireless access in vehicular environments (WAVE), also referred to as dedicated short-range communication (DSRC). It is an approved amendment to the IEEE 802.11 standard, whose protocol suite results from the combination of IEEE 802.11p and

IEEE 1609. The former focuses on physical and MAC layers for vehicular environments, while resource management, security, networking, and multichannel operation are handled according to the IEEE 1609 protocol suite.

IEEE 802.11p is based on the popular IEEE 802.11 Wi-Fi, exploiting the same medium access scheme based on the exchange of Request to Send/Clear to Send packets (RTS/CTS) – to alleviate packet collisions in case of unicast communications. However, this technique might not be enabled when a packet is sent in broadcast and the packet collision probability is consequently increased. Furthermore, the quality of service (QoS) support is provided by using the enhanced distributed channel access (EDCA) scheme, which cannot guarantee high packet delivery probability due to the huge number of collisions generated by high priority packets, characterized by a small and fixed contention window (CW) size. The entire 75 MHz bandwidth is divided into seven channels: one channel, i.e., control channel (CCH), is only used to convey emergency and safety traffic, while six service channels (SCH) are occupied by infotainment and multimedia traffic transmission. Further, a channel switching scheme allows the devices to tune to CCH during the CCH time interval and then switch to a specific service channel during the SCH interval.

ISO CALM

Continuous Air interface Long and Medium range (CALM) is the protocol suite standardized by ISO/TC 204 WG for Europe (Mohammad et al. 2011). The CALM CI (communication interface) provides all the functionalities to manage the physical and link layers and can support diverse wireless technologies, ranging from infrared communications to cellular and satellite communications. Moreover, the CALM networking layer coordinates network and transport layers and can either employ IPv6 mobility support protocols or the CALM FAST protocol to perform unicast and broadcast transmissions and store and forward operations.

C2C-CC

Car2Car Communication Consortium (C2C-CC) represents a European open industrial standard mostly focused on (non)safety applications development. It proposed the C2CNet architecture which is not completely IPv6 oriented while supporting multi-hop communications through ad hoc designed routing protocols and vehicles beaconing (Mohammad et al. 2011). Besides, it is inherently conceived for a multi-radio environment supporting both IEEE 802.11a/b/g/n, IEEE 802.11p and cellular technologies.

3G Systems

Presently, the third-generation (3G) networks have been widely deployed and adopted to enable mobile communications. In particular, 3G/UMTS (Universal Mobile Telecommunications System) operates in the band from 1.8 GHz to 2.5 GHz, basically providing data transfer speeds up to 2 Mbps. Besides, 3G HSPA (High-Speed Packet Access) offers a downstream data transfer rate of 14 Mbps and an upstream data transfer rate of 5.74 Mbps. In contrast, 3G HSPA+ (evolved HSPA) achieves 42 Mbps in the downlink and 11 Mbps in the uplink. 3G HSDPA (High-Speed Downlink Packet Access) technique was developed to meet the requirements of bandwidth-intensive applications such as large file transfers and fast Web browsing. It is an ideal technology to support real-time application due to its low latency (70 to 100ms) (Zhao et al. 2013).

To our purpose, it is worth noting that 3G systems provide vehicles with *ubiquitous* Internet access and data communication with other vehicles. These features might be highly beneficial to assist data delivery in VANETs. However, the cost of the 3G traffic is non-negligible, thus limiting their adoption for improving the performance of data delivery in VANETs while limiting the use of this technology to reduce the economical impact. For instance, 3G cellular networks have been commonly used for timely data dissemination to support VANET applications, such as accident prevention and traffic jam avoidance.

Finally, 3G provides an excellent *individual* mobility support, especially in terms of traditional horizontal handoff (OHO) (Lee et al. 2009). However a *seamless* vertical handoff (VHO) extension in order to handle the migration between *heterogeneous* networks is a necessary first step toward VANET, as well as the management of *group* and *constrained* mobility patterns.

4G Standards

The fourth generation (4G)'s most relevant features to VANET scenario are represented by an enhanced radio access technology (RAT) in terms of capacity and latency and a fine-grain spatial coverage via the introduction of *small cells* concept (Feteiha and Hassanein 2015). Nevertheless, the most promising characteristic is the so-called direct communication between devices which is supported under device to device communication (D2D), based on Long Term Evolution (LTE) and LTE-Advanced (LTE-A) (Gupta and Jha 2015; Shen 2015; Agiwal et al. 2016).

D2D paradigm was introduced D2D to reduce the load of evolved node B (eNB) by the 3rd Generation Partnership Project (3GPP) in its Release 12 addressing D2D discovery and communication. The main concept is that devices should be in proximity. D2D is one of the promising applications in terms of network control over communication sessions, where devices have to discover each other and directly communicate with *minimum* involvement of the network. This can solve the problem of delay present in V2V and time required to successfully establish communications as 4G is inherently an all Internet Protocol (IP) technology, which supports packet and circuit switching in its design. Different features were included to support communication systems and networks such as D2D communication which demonstrated its capability to handle V2V under different conditions. Besides, 4G supports high mobility of nodes with speed up to 350 Km/h that can be applied for V2V communication.

However, the spontaneous networking typical of V2V communities requires a dynamic spectrum management, as D2D is an LTE-enabled technology and devices will communicate by

reusing LTE resource. Specifically, the design consideration of D2D is to accommodate vehicles to operate in licensed band without causing harmful interference to licensed users, which can be easily controlled in terms of transmitted power level constraints for a V2V network operating in LTE spectrum (Sakr et al. 2015).

B4G Cellular Networks

Wide-area advanced 4G systems, especially Long Term Evolution – Advanced (LTE-A) cellular networks, are expected to directly support vehicular applications by means of self-organizing femto-cells, traffic shaping, and *vertical* roaming across different radio access technologies (RATs). In particular LTE networks have extensive coverage for urban and rural scenarios, with low latency and high capacity communications. In addition, LTE allows direct D2D communication which can be easily adopted between vehicles since LTE modems are already integrated into cars. Furthermore, 4G systems intrinsically guarantee long operative life, scalability, cost reduction, and higher performance, despite limitations on the radio access flexibility and on the resource allocation efficiency, especially in the case of sporadic data transmission. As a consequence, cellular systems are being adopted by numerous car manufacturers with the aim of offering diverse services, e.g., remote vehicle monitoring, infotainment, or assisted driving experience. However, though cellular networks are extensively deployed and can easily provide global coverage and ubiquitous connectivity, location-based broadcast applications with stringent requirements in terms of latency and reliability cannot be developed. In addition, a high vehicle density may overload access and core networks and affect the overall QoS of both user and vehicle traffic.

As previously addressed, along with the machine-type communication (MTC) definition, the 3rd Generation Partnership Project (3GPP) Release 12 introduces in LTE-A the support to device-to-device (D2D) or direct mode communications, enabling P2P transmission between devices in proximity (Astely et al. 2013).

This functionality fosters a new generation of devices able to communicate with each other, without any kind of human intervention and without involving the cellular infrastructure for the user plane. On the other hand, D2D communications pose also several challenges. First of all, direct mode communications should be established without affecting traditional communications via base station, i.e., by avoiding possible *interferences* with other devices. Secondly, peer and service discovery functionality need to be introduced, since a device is typically not aware of other terminals in the proximity. Following the paradigm of multi-hop cellular networks (MCN) (Nishiyama et al. 2014), D2D also provides more flexibility in a cellular network, as direct links enable the communication among the terminals using multiple hops.

5G Systems

Mobile network evolution is expected to converge by 2020 into the novel 5G system effectively integrating both wired and wireless segments to accomplish expanded use cases and applications (Wang et al. 2014; Boccardi et al. 2014). In particular, new services are expected such as the massive sensor and vehicular-to-everything communications, according to the Internet of Things (IoT) visions, which refers to interconnection and the autonomous information exchange among a *community* of generic devices. The latter aspect is involved with the so-called safety critical applications, requiring extremely low setup times and transmission delays. 5G is conceived as an unplanned *ultradense* system, where nodes are able to self-organize and to improve cell performance. This trend is clearly pointed out by the emphasis 3GPP working group is progressively posing on *small* cells, whose limit is represented by the D2D technology, providing an optimal coordination/cooperation among devices/cells. As the system is assumed to be inherently heterogeneous, a higher degree of flexibility is required for both radio access and backhaul networks. 5G systems are expected to offer native support for automotive-related

Evolution of Vehicular Networks in the Transition from 3G to 4G Systems, Fig. 3 VANET candidate protocol stack comparisons (Mohammad et al. 2011)

communications, provided that the LTE-V concept will be defined in Release 13 and 14 by taking into account the LTE-D aspects which facilitate the devices and services discovery and the infrastructure fault handling in a partial stand-alone network arrangement. To this purpose, VANET represents a relevant case study for 5G architecture, as it is highlighted by comparatively presenting WAVE, CALM, and C2C-CC functional stacks (Fig. 3).

Conclusions

In this entry, we provided an outlook on the potential impact of opportunistic ad hoc communication in VANET technologies

and applications, with a specific focus on VSNs. First, we analyzed the relevance of social aspects in vehicular applications and networking and the role of context awareness in VSNs in triggering appropriate adaptation actions at the application as well as at the communication level. Then, we reviewed candidate technologies both in the ad hoc and cellular domains that enable this paradigm shift with a special focus on the transition between 3G and 4G, embracing 5G standard evolution. We also characterized the D2D paradigm pointing out the relevant use cases where the benefits provided by multi-hop D2D communication schemes to emerging VSN applications could be provided in the near future.

Definition

The wireless sensor network (WSN) is a network of tens or hundreds of computing nodes (i.e., sensors) with various processing capabilities distributed over a large landscape. The communication inside the network is formed using wireless transmission techniques. The nodes have the capability to measure and process external environmental data and then send the data messages to a base station (BS) for further handling.

Historical Background

In the mid-1950s, the US Army developed the first WSN, called the “Sound Surveillance System (SOSUS),” for tracking and surveillance of Soviet submarines in the Atlantic and Pacific oceans. The earliest real-world project founded, in the 1970s, was the Automated Local Evaluation in Real Time (ALERT). It was designed to detect the existence of flood using sensors that take measurements as: temperature, humidity, rain, and water level (Golen et al. 2009). Recently, WSN is applied to civil applications, medical health care (Schwiebert et al. 2001), smart energy (Rupinder Kaur 2012), and industrial automation (Marketsandmarkets 2014). The global industrial wireless sensor network market size is estimated to grow from \$401.23 Million in 2013 to \$944.92 million by 2020. Figure 1 shows two layouts, a WSN military application proposed in Razaque and Elleithy (2014) and another layout for WSN health-care monitoring system presented in Saleem et al. (2011).

Foundation

To design a reliable WSN, many challenging parameters facing the design have to be considered as routing, deployment, and localization. WSN lifetime is considered one of the main challenges facing WSN design. The primary limiting factor for the sensor network is the energy supply which directly affects the WSN’s lifetime. WSN sensors are normally equipped with a lim-

ited capacity battery. Since the nodes could be deployed in hostile areas, it may be impossible to replace or recharge the nodes’ batteries. Thus, the design of the network must consider methods for maximizing the network lifetime and minimizing the energy consumption.

WSN clustering was proposed as a solution for the energy problem (Li et al. 2005; Vinay Kumar and Tiwari 2011; Liao and Zhu 2013). Clustering allows the network to work in a hierarchical manner. Therefore, WSN can incorporate efficient utilization of limited resources of the sensor nodes and extend its lifetime. Clustering process divides the network into disjoint groups called clusters. Each cluster elects only one node to become a cluster head (CH). Each CH is responsible for collecting sensed data from all nodes in the cluster group, concatenating it into a single message, and sending the data message to the BS (Khanna et al. 2006; Abbasi and Younis 2007). Clustering serves in reducing communication overhead (Patole 2012) and scalability and providing better use of network resources. The adoption of clustering as a technique for energy consumption and extending lifetime raises many design questions such as:

1. How many clusters should we have?
2. How many CH is adequate for a specific layout?
3. Which node should be elected as a CH?
4. Which cluster a node should join?

To answer the above-described questions, a powerful search algorithm needs to be used to explore the space of all possible design parameters described by these four questions. Traditional techniques, as the famous low-energy adaptive clustering hierarchy (LEACH) protocol (Heinzelman 2000), aimed to provide some answers of these questions in a random manner. However, they are expensive algorithms and suffer from nonuniformity in clusters and CH distribution (Hou et al. 2010).

Optimization algorithms were provided to solve various problems associated to WSN design and deployment (Madan et al. 2007). Among these algorithms are the Evolutionary

Extending WSN Lifetime Based on Evolutionary Clustering Algorithm, Fig. 1 Top image: WSN military application (Razaque and Elleithy 2014). Bottom image: WSN health-care monitoring (Saleem et al. 2011)

Algorithms (EAs) (Carballido et al. 2007; Mehr 2011; Sheta and Solaiman 2015). EA are algorithms with stochastic components that aim for finding optimal parameters for WSN design such as the adequate number of cluster heads (Solaiman and Sheta 2015b). EA are characterized by two major components: exploration and exploitation. Exploration enables the algorithm to diverse in the search space globally till it finds promising solution space. Exploitation refers to intensely search the promising region for a good solution. Putting great potential in exploitation leads to getting trapped in a local optimum solution, while using exploration reduces the chances of population convergence and causes deviation from the best solution. Therefore, EA has to maintain a good balance between exploration and exploitation to succeed in reaching a high-quality solution. EA performance is robust irrespective of the dimension of the search space (Golen et al. 2009; Martins et al. 2010). They can be implemented easily using any computer language and require minimal parameter tuning effort. However, there is no guarantee that optimal solutions can be reached. Genetic algorithm (GA), particle swarm optimization, (PSO), and differential evolution (DE) are well-known EA algorithms that have solved many optimization problems efficiently (Siew et al. 2012; Singh and Lobiyal 2012). A summary of these three algorithms is provided.

- Genetic algorithm was presented by J. Holland (1975) and extensively studied by Goldberg (1989; 2002), DeJong (1975; 1980; 1988), and others. GA successfully handled many areas of applications and was able to solve a wide variety of difficult numerical optimization problems. GA is inspired from Charles Darwin's theory of evolution: "the survival of the fittest" where only the best individuals are able to survive in harsh biological conditions. Thus, as generations run, better individuals are obtained by reproduction genetic operations as crossover and mutation of chromosomes.
- Particle swarm optimization was developed in 1995 (Kennedy and Eberhart 1995) by James Kennedy (social psychologist) and Russell Eberhart (electrical engineer). PSO is a robust stochastic nonlinear optimization technique based on movement and intelligence of swarms. It is inspired from social behavior of flock of birds or fish. The flock randomly search for food in an area by interacting together and following the nearest bird to the food. PSO consists of number of individuals, called particles. Each particle represents a possible solution. The particles move in the search space looking for the optimal solution. The particles update their position according the topology that allows each particle to exchange information with its neighborhood particles to memorize the best position reached by the swarm.
- Differential evolution is a very simple evolutionary algorithm that has been developed by Price and Storn in 1995 (Storn and Price 1997). DE is accurate and converges fast to the domain of optimal solution. It replaces classical crossover and mutation operators in GA with alternative operators. It attempts to replace crossover operator of GA by a special type of differential operator for reproducing offspring in the next generation. The population of DE is represented by its position in the search space, named vectors (Das et al. 2008). While GA relies on crossover, DE differs from GA in the order of operators used and uses mutation as the primary search mechanism.

Table 1 shows number of research work in the area of WSN clustering using EA. More details on WSN components and clustering algorithms are given in Solaiman and Sheta (2013). Hybrid EA clustering algorithms resulted in decreased computational effort and showed more adaptability to the dynamic nature of WSN (Solaiman and Sheta 2015,b).

Figure 2 shows part of the developed results in (Solaiman and Sheta 2015b; Sheta and Solaiman

Extending WSN Lifetime Based on Evolutionary Clustering Algorithm, Fig. 2 WSN lifetime for (a) 100 nodes and (b) 50 nodes with 2J initial energy

2015) describing the lifetime for WSN with 100 and 50 randomly deployed sensor nodes. The graphs show the EA's results in optimizing the WSN parameters (i.e., the number of sensors in each cluster, the selection of the number of CH, and the elected CHs) for a WSN with extended

lifetime compared to the LEACH protocol. EAs proved to a better layout and prolonging the WSN lifetime.

Key Applications

Extending WSN lifetime is major challenge that has to be considered in designing the network since the WSN applications are remotely deployed and battery replacement is impossible.

Fairness

Tian Lan

Electrical and Computer Engineering, George Washington University, Washington, DC, USA

Given a vector $\mathbf{x} \in \mathbb{R}_+^n$, where x_i is the resource allocated to user i , *how fair* is it? Consider two allocations among three users: $\mathbf{x} = [1, 2, 3]$ and $\mathbf{y} = [1, 10, 100]$. Among the large variety of choices for quantifying fairness, it is possible to have fairness values such as 0.33 or 0.86 for $\mathbf{x}$ and 0.01 or 0.41 for $\mathbf{y}$: $\mathbf{x}$ is viewed as 33 times more fair than $\mathbf{y}$, or just twice as fair as $\mathbf{y}$. How many such “viewpoints” are there? What would disqualify a quantitative metric of fairness? Can they all be constructed from a set of simple statements taken as true for the sake of subsequent inference?

Fairness of $\mathbf{x}$ can be quantified through a fairness measure, which is a function f that maps $\mathbf{x}$ into a real number. These measures are sometimes referred to as diversity indices in statistics. Various fairness measures have been proposed throughout the years. These range from simple ones, e.g., the ratio between the smallest and the largest entries of $\mathbf{x}$, to more sophisticated functions, e.g., Jain’s index and the entropy function. Some of these fairness measures map $\mathbf{x}$ to a normalized range between 0 and 1, where 0 denotes the minimum fairness, 1 denotes the maximum fairness (often corresponding to an $\mathbf{x}$ where all x_i

are the same), and a larger value indicates more fairness. For example, min-max ratio (Marson and Gerla 1982) is given by the maximum ratio of any two user’s resource allocation, while Jain’s index (Jain et al. 1984) computes a normalized square mean. How are these fairness measures related? Is one measure “better” than any other? What other measures of fairness may be useful?

An alternative method that has gained attention in the networking research community since (Kelly et al. 1998; Mo and Walrand 2000) is the optimization-theoretic approach of α -fairness and the associated utility maximization problem. Given a set of feasible allocations, a maximizer of the α -fair utility function satisfies the definition of α -fairness. Two well-known examples are as follows: a maximizer of the log utility function ($\alpha = 1$) is proportionally fair, and a maximizer of the α -fair utility function as $\alpha \rightarrow \infty$ is max-min fair. More recently, α -fair utility functions have been connected to divergence measures (Uchida and Kurose 2009). In Bonald and Massoulié (2001); Massoulié and Roberts (2002), the parameter α was viewed as a fairness measure in the sense that a fairer allocation is one that is the maximizer of an α -fair utility function with larger α – although the exact role of α in trading-off fairness and throughput can sometimes be surprising (Tang et al. 2006). While it is often believed that $\alpha \rightarrow \infty$ is more fair than $\alpha = 1$, which is in turn more fair than $\alpha = 0$, it remains unclear what it means to say, for example, that $\alpha = 3$ is more fair than $\alpha = 2$.

There are in general two main approaches to fairness evaluation: binary (is it fair according to a particular criterion, e.g., optimization objective, proportional fair, no-envy?) or continuous (quantifying how fair is it, and how fair is it relative to another allocation?). In the latter case, there are three sub-approaches:

- (A) A system-wide, global measure: (A1) $f(\mathbf{x})$ where f is our fairness function, or (A2) $f(U_1, U_2, \dots, U_n)$ where U_i is a utility function for each user that may depend on the entire $\mathbf{x}$.
- (B) Individual, global measures: the set of $\{f_i(\mathbf{x})\}$ (each user i cares about the entire allocation $\mathbf{x}$).
- (C) Individual, local measures: the set of $\{\tilde{f}_i(x_i)\}$ (user i only cares about her resource via some function $\tilde{f}_i$).

Renyi entropy. Renyi entropy is a family of functionals quantifying the uncertainty or randomness of generalized probability distributions, developed in 1960 (Renyi 1960). Renyi entropy is derived from a set of five axioms as follows:

- 1. Symmetry.
- 2. Continuity.
- 3. Normalization.
- 4. Additivity.
- 5. Mean-value property.

Renyi entropy, a generalization of Shannon entropy, has been further extended by others since the 1960s, e.g., smooth Renyi entropy for information sources (Renner 2005) and quantum Renyi entropy (Renner and Wolf 2004).

Lorenz Curve. Schur-concavity of fairness measures is a critical property for justifying fairness measures by establishing an ordering on the set of Lorenz curves (Aaberge 2001). Let $P_{\mathbf{x}}(y)$ be the cumulative distribution of a resource allocation $\mathbf{x}$. Its Lorenz curve $L_{\mathbf{x}}$, defined by

$$L_{\mathbf{x}}(u) = \frac{1}{\mu} \cdot \int_{\{P_{\mathbf{x}}(y) \leq u\}} y dP_{\mathbf{x}}(y), \quad (1)$$

is a graphical representation of the distribution of $\mathbf{x}$ and has used to characterize the social welfare distributions and relative income differences in economics. In 2001, an axiomatic characterization of Lorenz curve orderings is proposed based on a set of four axioms (Aaberge 2001):

- 1. Order. (The ordering is transitive and complete.)
- 2. Dominance. (The ordering is Shur-concavity.)
- 3. Continuity.
- 4. Independence.

Cooperative Economic Theories. In economics, a number of theories have been developed to study the collective decisions of groups. Many of these theories have also been uniquely associated with sets of axioms Moulin (1991), including two well-known axiomatic constructions: the Nash bargaining solution in 1950 (Nash 1950) and the Shapley value in 1953 (Shapley 1953).

The Nash bargaining solution was developed from a set of four axioms:

- 1. Invariance to affine transformation.
- 2. Pareto optimality.
- 3. Independence of irrelevant alternatives (IIA).
- 4. Symmetry.

Nash's axiom of IIA contributes most to his uniqueness result, and it is also often considered as a value statement. It has been shown by many others that replacing IIA with other value statements may result in solution classes different from the bargaining solution. Given a feasible region of individual utilities, the Nash bargaining solution is also equivalent to a maximization of the proportional fairness utility function.

Another well-known solution concept in economic study of groups is the Shapley value (Shapley 1953). In a coalition game, individual decides whether or not to form coalitions in order to increase the maximum utility of the group while ensuring that their share of the group utility is maximized. The Shapley value concerns an operator that maps the structure of the game, to a set of allocations of utility in the overall group.

Given a coalition game, four axioms uniquely define the Shapley value:

1. Pareto Optimality.
2. Symmetry.
3. Dummy.
4. Additivity.

Ultimatum Game. Cake-Cutting and Fair Division: In ultimatum game (Nowak et al. 2000), player A divides a resource into two parts: one part for herself and the other for player B. Player B can then choose to accept the division or reject it, in which case neither player receives any resource. Without a prior knowledge about player B's reaction, player A may divide anywhere between $[0.5; 0.5]$ and $[1; 0]$. Running this game as a social experiment in different cultures have led to debates about the exact implications of the results on people's perception on fairness: how fair does it take for player B's perception, and player A's guess of that, to accept player A's division? This has also been contrasted with the perception of fairness in the related dictator game (Ben-Ner et al. 2004; Bolton et al. 1998), where player B has no option but to accept the division by player A.

A classic generalization of ultimatum game that has received increasing attention in the past decade is the cake-cutting problem. As reviewed in books (Barbanel 2005; Brams and Taylor 1996), the cake is a measure space, and each player uses a countably additive, non-atomic measure to evaluate different parts of the cake. Among the work studying the cake-cutting problem, e.g., (Brams and Taylor 1995), the primary focus has been on two criteria: efficiency (Pareto optimality) and fairness (envy-freeness). Achievability results for four users or more are still challenging.

Fairness in cake-cutting and fair division is traditionally defined as envy-freeness. It is a binary summary based on each individual's local evaluation: the allocation of cake is fair if no user wants to trade her piece with another piece. In (Brams et al. 2006), this restrictive viewpoint on fairness is expanded to include proportional allocation of the left-over piece after each user gets $1/n$ th of

the cake (in her own evaluation). It is shown that Pareto optimality and proportional sense of fairness may not be compatible for three players or more.

Rawls' Theory of Justice and Distributive Fairness. In political philosophy, the work of Rawls has been both influential and provocative since the original publication in 1970 (Rawls 1971). Rawl's theory of justice concerns mostly with liberties, which are not exactly the same as resources. However, one may also read his theory as a qualitative framework for distributive fairness in allocating limited resources among users. The arguments posed by Rawls are based on two fundamental *principles* (axioms stated in English),

1. "Each person is to have an equal right to the most extensive scheme of equal basic liberties compatible with a similar scheme of liberties for others."
2. "Social and economic inequalities should be arranged so that they are both (a) to the greatest benefit of the least advantaged persons, and (b) attached to offices and positions open to all under conditions of equality of opportunity."

The first principle governs the distribution of liberties and has priority over the second principle. One may interpret it as a principle of distributive fairness in allocating limited resources among users. Next, the first part of Rawls second principle concerns with the distribution of opportunity, while the second part is the celebrated "difference principle": an approach different from strict egalitarianism (since it is on the absolute value of the least advantaged user rather than the relative value) and utilitarianism (when narrowly interpreted where the utility function does not capture fairness).

Normative Economics and Welfare Theory. Rawls theory also has intricate interactions with normative economics, where many results are analytic in nature [68]. In addition to stochastic dominance, Arrow's impossibility theorem, and the cooperation game theories of Nash and of

Shapley, there are several major branches (Atkinson 1970; Kolm 1969; Sen 1973). Another set is the ethical axioms of transfers. For example, the Pigou-Dalton principle states that inequality decreases via Robin Hood operation that does not reverse relative ranking. The principle of proportional transfers states that what the donor gives and the beneficiary receives should be proportional to their initial positions.

Bergson-Samuelson social welfare function (Dworkin 1981; Bergson 1938) $W(U_1(\mathbf{x}), \dots, U_n(\mathbf{x}))$ aims at enabling complete and consistent social welfare judgment on top of individual preference-based utility functions U_i . Kolm's theory of fair allocation (Kolm 1972) uses the criterion of equity as no-envy, and it is well-known that competitive equilibrium with equal budget is the only Pareto-efficient and envy-free allocation if preferences are sufficiently diverse and form a continuum (Varian 1976).

Sociology and Psychology: Inequality Indices.

Quantifying inequality/injustice/unfairness using individual, local measures has been pursued in sociology. For example, Jasso in 1980 (Jasso 1980) advocated justice evaluation index as log of the ratio between actual allocation and just allocation. Allocation can be done either in quantity or in quality (in which case ranking quantifies the quality allocation). Many properties were derived in theory and experimented with in data about income distribution in different countries (Jasso 2007). In particular, probability distribution of the index is induced by the probability distribution of the allocation. This index is derived based on two principles and three laws in the paper, including equal allocation maximizes justice, and aggregate justice is arithmetic mean of individual ones.

In Jasso (1999), two other injustice indexes, JI1 and JI2, were developed based on the above. One interesting feature is that JI1 differentiates between under-reward and over-reward as two types of injustice. Another useful feature is the decomposition of the total amount of perceived injustice into injustice due to scarcity and injustice due to inequality. They are further unified with Atkinson's measure of inequality (Atkinson

1970): 1 minus the ratio of geometric mean and arithmetic mean. At the heart of these indices is the approach of taking combinations of arithmetic and geometric means of an allocation to quantify the spread.

Lan-Chiang fairness theory. Many existing approaches for quantifying fairness are different. On the one hand, α -fair utility functions are continuous and strictly increasing in each entry of $\mathbf{x}$; thus, its maximization results in Pareto optimal resource allocations. On the other hand, scale-invariant fairness measures (ones that map $\mathbf{x}$ to the same value as a normalized $\mathbf{x}$) are unaffected by the magnitude of $\mathbf{x}$, and an allocation that does not use all the resources can be as fair as one that does. Can the two approaches be unified? To address the above questions, Lan and Chiang develop an axiomatic approach to fairness measures (Lan et al. 2010). It is shown that a set of five axioms, each of which simple and intuitive, thus accepted as true for the sake of subsequent inference, can lead to a useful family of fairness measures, i.e.:

1. Continuity.
2. Homogeneity.
3. Saturation.
4. Partition.
5. Starvation.

Starting with these five axioms, a unique family of fairness measures are generated from generator functions g : any increasing and continuous functions that lead to a well-defined "mean" function (i.e., from any Kolmogorov-Nagumo function Kolmogoroff 1930; Aczél 1948). Using power functions with exponent β as the generator function, a unique family of fairness measures are derived, i.e.:

$$f_{\beta, \lambda}(\mathbf{x}, \mathbf{q}) = \text{sign}(-1 - \beta) \cdot \left(\sum_i x_i \right)^{1/\lambda} \cdot \left[\sum_{i=1}^n q_i \left(\frac{x_i}{\sum_{j=1}^n x_j} \right)^{-\beta} \right]^{\frac{1}{\beta}}. \quad (2)$$

Fairness, Fig. 1 $F_{\beta,\lambda}$ unifies different fairness measures from diverse disciplines

This result unifies many existing fairness measures: Generalized Jain's index is a special case of $F_{\beta,\lambda}(\mathbf{x})$ for $1/\lambda = 0$ and $\beta < 1$; inverse of p -norm is another subclass of $F_{\beta,\lambda}(\mathbf{x})$ for $\beta \leq -1$; and α -utility is obtained for $1/\lambda = \beta/(1 - \beta)$ and $\beta > 0$. New fairness measures are revealed corresponding to other ranges of β and λ . The degree of homogeneity $1/\lambda$ determines how $F_{\beta,\lambda}(\mathbf{x})$ scales as throughput increases, while β provides trade-off between "resolution" and "strictness" of the fairness measure. The unification is illustrated in Fig. 1, including all known fairness measures that are global (i.e., mapping a given allocation vector to a single scalar) and decomposable (i.e., subsystems fairness values can be somehow collectively mapped into the overall systems fairness value).

[Robustness of smart grids](#)

Definitions

Electrical power grids are the backbone of the modern society. Since every aspect of our life depends on electricity, it is of utmost importance that the power grid infrastructure is highly reliable and always available. *Smart Grid* promises this by integrating the power grid and communication network. We can think of a smart grid as an interconnected network of power stations and communication centers. The interactions between these entities have important consequences on the resilience of smart grids. The failure of a small number of nodes can result in a cascading failure of a large number of nodes, which can bring the entire network down. Such grid failures have occurred in recent past in North America, Italy, and India. The effect of random and targeted attacks can lead to very different type of cascading failures. In this entry, we discuss different network models of smart grids and their impact on the reliability and availability. We believe that in order to design a robust smart grid, it is important to understand the interconnections amongst the different elements of the smart grid and the effect of one network on the other, under failure and attacks.

Introduction

A *smart grid* is an electrical power grid that uses information and communications technology (ICT) to automate the operations and to improve the efficiency, reliability, and sustainability of the production, transmission, and distribution of electricity. It is also sometimes referred to as an *intelligent power grid*.

The term smart grid was first used by Michael T. Burr (2003). These systems use bidirectional communication technology and computer processing that has been used for many years in other industries. They offer several benefits to utilities and consumers, resulting in big improvements in energy efficiency on the electricity grid and in homes and offices.

Smart grid integrates power grid and communication network. The power network consists of power plants, distribution stations, and electrical devices. A communication network consists of sensors to sense information, processing stations to process data and control stations. A key feature of the smart grid is the automation technology that lets the utility adjust and control each individual device or millions of devices from a central location.

Need for Designing Robust Smart Grids

Reliability of power grids is a very important consideration during its design and operation. In the USA, the annual cost of outages in 2002 is estimated to be \$79 billion, which is about a third of the total electricity revenue of \$249 billion.

In recent years, there have been some major blackouts in different parts of the world, affecting millions of people and causing losses to the tunes of billions of dollars to homes and businesses. We look at three such important blackouts. In each of these cases, the outage spreads a large area because of cascading failure of power grids.

1. **2003 blackout of USA and Canada:** The Northeast blackout of 2003 was a widespread power outage that occurred on Thursday, August 14, 2003, throughout parts of the Northeastern and Midwestern USA and the Canadian province of Ontario. At the time, it was the second most widespread blackout in history, after the 1999 Southern Brazil blackout. The blackout affected an estimated 10 million people in Ontario and 45 million people in 8 US states.
2. **2003 Italy blackout:** The 2003 Italy blackout was a serious power outage that affected all of Italy, except the islands of Sardinia and Elba for 12 h, and part of Switzerland near Geneva for 3 h on 28 September 2003. It was the largest blackout in the series of blackouts in 2003, affecting a total of 56 million people. It was also the most severe blackout in Italy in 70 years.
3. **2012 India blackout:** The July 2012 India blackout was the largest power outage in history, occurring as two separate events on July

30 and July 31 in 2012. The outage affected over 620 million people, about 9% of the world population, or half of India's population, and spread across 22 states in Northern, Eastern, and Northeast India. An estimated 32 gigawatts of generating capacity was taken offline in the outage.

Maintaining the reliability of power grids is becoming a major challenge due to the following reasons.

- Grid congestion due to uncertainty, diversity, and uneven distribution of energy supplies.
- Transmission of large amount of power over long distances increasing volatility and reducing reliability.
- Increasing energy consumption and higher level of peak demand.
- Aging infrastructure and less investment for maintenance.
- Maximizing utilization using modern tools for monitoring, analyzing, and control.
- Very high utilization of distributed resources increasing complexity and vulnerability of the grid.

Types of Faults in Smart Grids and Measures to Prevent Them

A smart grid is susceptible to various types of faults. These include overloading of grid, electrical and mechanical failures of generators and substations, sabotages, and terrorist attacks. Failures can occur because of incorrect routing algorithms.

In modern network topologies, message delivery failure may be avoided through smart routing technologies that can bypass faulty routers and links. Such fault tolerance is possible only when the faulty equipment does not constitute a single point of communication failure. Therefore, it is important to maintain redundant pathways through the network.

In order to build a reliable smart grid, it is important not only to identify the vulnerabilities but also study the structure of smart grid networks. Since a smart grid consists of millions of devices, it is important to understand how these

are interconnected. An attack/failure can affect one node, which in turn will affect other nodes and this process follows in a cascading way. In this entry, we therefore study the structure of the underlying smart grids. We model a smart grid as an interdependent complex network. Complex networks have been widely studied by computer scientists, mathematicians, physicists, biologists, and sociologists to model many real-world networks like social networks, biological networks, ad hoc networks, and citation networks (Pal and Ruj 2015). The complex network of power grid has been studied in great details (Pagani and Aiello 2013). However, the structure of smart grid is very different from that of a power grid, in that it consists of two networks which are interconnected. In order to build a robust smart grid, we therefore study the structure of individual networks, their interconnection and cascading failure between these two networks.

We model the structure of smart grids as interdependent networks in the section “[Structure of Interdependent Smart Grid Networks](#).” We discuss cascading failures in smart grids in the section “[Cascading Failures](#).” Attack models are presented in the section “[Attacks on Smart Grids](#)” along with measures of resilience. We look at techniques to increase resilience of networks in the section “[Improving the Resilience of Smart Grids](#).” We perform a comparative study of proposed models in the section “[A Comparative Study of Proposed Models](#)” and present experimental results. We conclude in the section “[Conclusion and Future Direction](#)” with some open problems and future directions.

The Smart Grid as an Interdependent Network

Before studying the structure of smart grid, we give a brief idea about complex networks.

Structure of Complex Networks

Networks occurring in real life have random structures and can be represented by some well-known graphical models. Degree distribution of

the graph G is the probability distribution of degrees of the vertices in G .

Probability that a node has degree k is calculated by dividing the number of nodes of degree k with the total number of nodes in the network. One of the earliest and simplest models is *Erdos-Renyi* (ER) random graph model. A graph $G(n, p)$ is called an Erdos-Renyi random graph if the graph consists of n vertices and every edge occurs with a probability p . We can also think of it as a graph $G(n, m)$, which is chosen uniformly at random from the set of all possible graphs on n vertices and m edges. The degree distribution of ER graph is Poissonian. For a large number of nodes, the degree distribution follows a normal distribution, which has a bell-shaped curve, when the degree k is plotted against the number of nodes of degree k .

Real-world networks like the Internet, World Wide Web, citation networks, and metabolic networks do not have a Poisson distribution (Pal and Ruj 2017). The degree distribution of such networks follows a power law distribution. In a power law degree distribution, the degree distribution is given by $P(k) \propto k^{-\alpha}$, where α is a constant ($1 \leq \alpha \leq 3$). Such networks are also known as scale-free (SF) networks. In such networks, there are many nodes with small degree and a very few high degree nodes. The high degree nodes are called hubs. The degree distribution decays slowly as the degree increases and gives rise to heavy tailed curve. Another class of networks has exponential degree distribution. Exponential degree distribution means that the probability that a node has degree k is given by $P(k) \propto e^{-\lambda k}$, where λ is a constant. The curve has a faster decay than power law distribution. Social networks exhibit *small-world* property. *Small-world networks* have small average path length between nodes.

From prior observations (Pagani and Aiello 2013), it is known that the power grid has either a power law degree distribution or exponential degree distribution. For example, the US power grid has exponential degree distribution, whereas the Italian power grid has power law degree distribution. The communication network follows a power law degree distribution according to the

results given in Huang et al. (2013), Dong et al. (2012) and Ruj and Pal (2014).

Structure of Interdependent Smart Grid Networks

An *interdependent network* is a network consisting of two subnetworks, where the nodes in each of the subnetworks depend on the nodes in the other subnetwork. The links across networks are called *dependency links* or *interlinks*, which are in addition to the links within the two subnetworks (also called *intralinks*). Since networks rarely appear in isolation, an interdependent network is a more realistic way to model network structures formed in real life. Interdependency between networks can explain events like the 2003 Italy blackout.

We represent a smart grid interdependent network as a graph $G_{SG} = (V_{SG}, E_{SG})$, consisting of two disjoint subnetworks represented by directed subgraphs $G_C = (V_C, E_C)$ and $G_P = (V_P, E_P)$. They denote the communication network and the power network, respectively. The number of nodes in the communication network and the power network are $|V_C| = n_C$ and $|V_P| = n_P$, respectively. The interlinks E_{PC} have one endpoint in V_C and the other endpoint in V_P . Thus, $E_{PC} = \{uv : u \in V_C, v \in V_P\} \cup \{uv : u \in V_P, v \in V_C\}$, and $E_{SG} = E_P \cup E_C \cup E_{PC}$.

There are different ways in which interlinks can be assigned between the nodes of the two networks. Power and communication nodes can be linked one-one, or can be linked many-one, or many-many. A power node must be controlled by at least one communication node, whereas a communication node must be powered by at least one power node. Depending on this, the in-degree of power and communication node both must be at least one. There can be added restrictions, where each communication node controls exactly one power node (out-degree of communication node is one), whereas, each power node supplies power to one or more communication nodes (out-degree of power node is at least one). The network structure and assignment of interlinks determine robustness.

In Fig. 1, we model the smart grid as an interdependent network of communication network

Fault Tolerance and Reliability of Smart Grids, Fig. 1
The smart grid as an interdependent complex network (Ruj and Pal 2014)

and power network. There are directed edges from communication nodes to power nodes and vice-versa. The links within each subnetwork are undirected edges. The structure of intralinks and interlinks together determine the resilience of the smart grid.

Fault Tolerance in Smart Grids

Cascading Failures

Electrical blackouts often occur in power grids because of cascading failures. In a *cascading failure* in an *interdependent network*, when a node fails in one network G_P , the nodes on the other network G_C which are dependent on this node also fail. Consequently, the nodes in G_P which are dependent on these nodes fail and the process continues recursively. Due to cascading failures, a large portion of a network can go down within a short amount time, even when a small fraction of nodes fail initially. This is a serious threat to the efficient operation of a network.

How Does It Occur?

We consider the example in Fig. 2. Initially, the node x in the power network G_P fails. As a result,

Fault Tolerance and Reliability of Smart Grids, Fig. 2 Illustration of cascading failure in interdependent smart grid networks. The faulty nodes are shown as double circles

the nodes y and z in the communication network G_C fail, because they lose the interlink from node x . Next, node u in G_P fails, as it becomes an isolated node. Then, node v in G_C fails as it becomes an isolated node. The cascading failure stops at this point, and the final network is shown in Fig. 2f.

Attacks on Smart Grids

A smart grid can be attacked in many different ways. Here, we are assuming an adversarial model, meaning that there is an adversary who is trying to cause node and/or edge failures to disrupt the functioning of the network. There can be many cybersecurity attacks on smart grids, like denial-of-services (DoS) attacks, network intrusion, compromising communication equipments, and interception. The details can be found in Mo et al. (2012). Here we consider node compromise under random, targeted, and adaptive attacks.

Random Attacks

In a random attack, the adversary selects a vertex/edge uniformly at random from the collection of all possible vertices/edges and makes it faulty. When a vertex becomes faulty, the vertex along

with all the edges incident on it is removed from the network.

Targeted Attacks

In a targeted attack, the adversary selects a vertex with a probability proportional to its degree (or some other parameter such as betweenness centrality or clustering coefficient) and makes it faulty. Our intuition suggests that if high-degree nodes are removed, the network disintegrates faster than if nodes are removed at random. Betweenness of a node is the number of shortest paths that pass through the nodes. Compromising a high-degree node disrupts a large number of paths between nodes, thus disconnecting them. High clustering coefficient means that the neighbors of a node are highly likely to be neighbors themselves.

Adaptive Attacks

In adaptive attacks, the attacker deletes nodes iteratively in rounds, instead of all nodes at once. In each round, the attacker chooses a set of nodes to be compromised based on the new centrality measure and compromises this set. It has been observed (through experiments) that an adversary has an advantage while compromising nodes adaptively, compared to nonadaptive deletion.

Measuring Robustness of Smart Grid Networks

Having modeled a smart grid as a complex interdependent network, we are now in a position to define the different measures of robustness. One way of doing this is to find the fraction of nodes in the *giant component* that survived the attack. The giant component is a connected component having a constant fraction of nodes of the original network. In other words, if there are n nodes in the network, a giant component has $O(n)$ nodes. Robustness can thus be calculated by finding the size of the giant component, if it exists. If a giant component does not exist after an attack, then we can say that the network is not resilient to attacks.

We can also measure robustness by the fraction of nodes that can be attacked, in order to maintain a giant component. It has been observed that there is a threshold at which a network crumbles down. This means that if we compromise fewer nodes, then there will be a giant component. However, above this value, the network disintegrates. The fraction of nodes surviving when transition takes place is called the *critical probability*.

Though we want nodes to connect to each other using small hops, it might so happen that after an attack, two nodes are still connected by a very long path. Connectivity is preserved, but the distance between nodes becomes substantially large. Resilience can be measured by studying the size of the giant component of small diameter, if there exists any.

Another measure is the average path length in a network. The *average path length* is the shortest path length between two nodes averaged over all possible node pairs. The shorter the average path length, the better connected the network is, and hence more fault tolerant.

Improving the Resilience of Smart Grids

The most important question is to decide the structure of the network, which will make the smart grid robust. One way to achieve this is to find a proper assignment of interlinks. One might think that increasing the number of interlinks

might increase the robustness. However, if nodes of high degree are compromised, the smart grid might collapse. The cost of maintaining large number of interlinks is also very high. Thus, on one hand we have the problem of increasing robustness, and on the other hand is the problem of cost. So, we need to have a trade-off between the two.

Apart from increasing the number of interlinks, we can change the structure of the networks. The current literature (Ruj and Pal 2014; Dong et al. 2012) suggests the use of scale-free (SF) networks for both power and communication. One reason is that, some power grids are known to be scale-free. However, there are no reasons to believe that SF-SF combination will result in better resilience to attacks. As shown in Ruj and Pal (2014), SF networks are more prone to targeted attacks than ER networks. The question is then, what should be the structure of the power network and communication network, which will guarantee high resilience in case of both random and targeted attacks.

There has been some work on mitigating attacks in power networks (Schneider et al. 2011; Wang et al. 2012). These papers study the structure of networks that improves resilience. For example, Schneider et al. (2011) increases the resilience of networks by swapping edges. Suppose there are two edges ab and cd . Edges are swapped, resulting in ac and bd . If this swapping increases the resilience, then this configuration is considered. Else, the old configuration is preserved. This results in the network structure which looks like an onion, with high-degree nodes at the center and low-degree nodes at the periphery.

Apart from making structural changes to networks, we can also look at easy ways to identify and stop cascading failures. A recent paper Kaplunovich and Turitsyn (2013) presents an algorithm which identifies dangerous pairs of failures in power grids and prunes them in an efficient manner. The algorithm performs very well for medium size power networks consisting of about 3000 nodes and prunes 99% of failure nodes in just 10 min. Ruj and Pal (2016) initiated the study of preferential attachment model with degree bound. They apply this idea to the key

predistribution problem in wireless sensor networks (WSN) and smart grids.

Huang et al. (2015) studied the effect of cascading failures in interdependent complex networks (smart power grids, automated traffic control systems, wireless sensor, and actuator networks) using percolation theory. The physical resource and computational resource networks are connected and mutually dependent. The failure in the physical resource network might cause failures in the computational resource network, and vice versa. A small failure in either of them could trigger cascade of failures within the entire system. They did a thorough mathematical analysis of failure propagation in the system. Their mathematical analysis proves that there exists a threshold for the proportion of faulty nodes, above which the system collapses. Using extensive simulations, they determine the critical values for different system parameters.

A Comparative Study of Proposed Models

We now study the existing models of smart grids that have been proposed so far. We present them in Table 1. The table describes the type of networks that have been considered so far, the interconnection patterns, the attack models and countermeasures, and the important contributions. Most of the papers (Huang et al. 2013, Dong et al. 2012; Ruj and Pal 2014; Parandehgheibi and Modiano 2013) consider smart grids exclusively; (Yagan et al. 2012) discusses cyber-physical systems with emphasis on smart grids, (Schneider et al. 2011; Wang et al. 2012) discuss power grids. Most of the papers consider the same type of networks, ER-ER or SF-SF. Buldyrev et al. (2010) initiated the study of interdependent networks. They considered random attacks on networks of same size and one-one assignment of interlinks. They pointed out that SF-SF interdependent networks

are less robust than single SF networks. Yagan et al. (2012) studied ER networks, where each node has the same inter-degree. They show that such a regular allocation of links is more robust to failures than random assignment of links. Huang et al. (2013, Dong et al. 2012) considered smart grids with SF-SF power-communication networks and studied the percolation threshold. They conducted extensive experiments by random node compromise to show that the estimated percolation threshold depends on the power law exponent. They also gave estimates of cost vs. robustness. Adding more interlinks increases robustness but is costly. Ruj and Pal (2014) studied targeted attacks on smart grids and showed that the SF-SF networks are more prone to targeted attacks than ER-ER networks. Compromising a small fraction of high-degree nodes disintegrates the network, i.e., it does not have a giant component.

The problem of interdependent smart grids has been modeled in (Nguyen et al. 2013; Sen et al. 2014) as layered graphs with power and communication graphs at the two layers. In Nguyen et al. (2013), the authors have considered the problem of finding the set of nodes that has to be removed to minimize the number of nodes in the largest connected component. This problem is called *Interdependent Power Node Disruptor* (IPND), and it has been shown to be NP-Hard. They show that this problem cannot be approximated better than a factor of $(2 - \epsilon)$ to the optimum. They have given a greedy algorithm to solve IPND. Sen et al. (2014) have shown that there exist polynomial time algorithms for the above problem in special cases of interconnection. One such case is when a power node depends on a single communication node and vice versa.

Parandehgheibi and Modiano (2013) studied a simple version of smart grids in which all power nodes are connected to a main hub and all communication nodes are connected to a main control center, thus forming a star-like structure. They proposed an algorithm to identify the minimum number of nodes that will disconnect the whole network.

Experiments on Interdependent Networks and Implications

In this section, we look at experimental results on interdependent smart grids. We consider different types of interdependent networks like ER-ER and SF-SF, of different sizes and different interconnection patterns. We study random and targeted attacks on these networks. We show that SF-SF graphs are more vulnerable to targeted attacks than ER-ER graphs. The experiments have been performed using the network library *igraph* (Csardi and Nepusz 2006) on C. *igraph* has inbuilt packages for performing different functions like finding giant components, average path lengths, and betweenness.

In Fig. 3, the power network consists of 1000 nodes and the communication network consists of 10,000 nodes, following the conventions of Ruj and Pal (2014) and Dong et al. (2012). The communication/power network is generated as a scale-free network using a power-law degree distribution. Interlinks have been assigned randomly from communication to power network. We have plotted the size of the giant component (as a fraction of the size of the communication/power network) against the number of nodes attacked in the communication network. In targeted attacks, high-degree nodes are compromised with higher probability. We have considered three types of attacks on communication network: random, targeted, and mixed (50% nodes compromised ran-

domly and 50% compromised based on their degree). It is observed that for a given value of the number of attacked nodes, the fraction of nodes in the giant component of the communication network is highest for random attacks and lowest for targeted attacks. The corresponding fraction for mixed attacks lies somewhere in the middle. We also see that for the same fraction of nodes compromised, the giant component of the power network disintegrates faster for targeted attacks, compared to random attacks. We see that on compromising 2200 nodes, there is no giant component when targeted attack occurs, whereas giant component exists, under random attacks. This is expected, as attacking higher degree nodes result in a faster disintegration of the network, resulting in smaller components. A similar result is expected when we consider betweenness instead of degree, i.e., compromise nodes of high betweenness compared with high probability.

In Figs. 4 and 5, the communication network consists of 2000 nodes, whereas the power network consists of 1000 nodes. In Fig. 4, we have plotted the size of the giant component (as a fraction of the size of the communication network) against the number of attacked nodes, where as, in Fig. 5, we have plotted the size of the giant component (as a fraction of the size of the power network) against the number of attacked nodes. The communication network and power networks

Fault Tolerance and Reliability of Smart Grids, Fig. 3 Variation of giant component size with number of attacked nodes for targeted, random, and mixed attacks

Fault Tolerance and Reliability of Smart Grids, Fig. 4 Variation of giant component size with number of attacked nodes in the communication network for scale-free and Erdos-Renyi models

Fault Tolerance and Reliability of Smart Grids, Fig. 5 Variation of giant component size with number of attacked nodes in the power network for scale-free and Erdos-Renyi models

are generated using (1) a scale-free (SF) network using a power-law degree distribution, (2) the Erdos-Renyi (ER) $G(n, p)$ model with $p = 0.01$, and (3) the Erdos-Renyi (ER) $G(n, p)$ model with $p = 0.005$. Only nodes in the communication network are attacked. In Fig. 5, we have plotted the size of the giant component (as a fraction of the size of the power network) against the number of attacked nodes. From Figs. 4 and 5 we see that, for all the three types of attacks, the sizes of the giant components for ER graphs

are comparable. The power and communication networks will be more fault tolerant to targeted attacks for Erdos-Renyi networks, compared to scale-free networks.

Conclusion and Future Direction

In this entry, we discussed how power grids can become faulty and the different ways in which they can be attacked. We modeled the smart grid

as an interdependent network of a communication network and a power network. In future, the smart grid will be connected to the Internet of Things (IoT), so there might be more than two networks to consider. We studied some real-world scenarios where cascading of faults led to a catastrophic failure of a large portion of the smart grid. We discussed ways to measure the robustness of a smart grid. We also considered various strategies to design the networks so that the effect of attacks can be effectively neutralized. The structure of the communication network and the power network, and the interconnection pattern between the two can have a profound effect on the reliability of a smart grid. We need to study further to have a better understanding of the network structure on the fault-tolerance of a network.

Fingerprint-based positioning; RSSI-based positioning; Wi-Fi localization

Definition

Fingerprinting localization refers to a series of positioning techniques for localizing and tracking radio frequency (RF) devices by employing received signal strength (RSS) or received signal strength indicator (RSSI). They generally contain two phases: online phase and offline phase. In the first phase, RSS values of different beacons are measured on different reference locations in the area of interest. These values will be stored in a database. In the second phase, the target RF device can measure an RSS vector and compare this vector to those in the database. The positioning result will be the coordinate of the closest RSS vector or the weighted coordinate of several closest RSS vectors.

Historical Background

GPS has been a very successful positioning system for several decades. However, this system is not available in some scenarios, e.g., indoor environments. As alternatives to GPS, many different localization techniques have been proposed,

based on time of arrival (ToA), time difference of arrival (TDoA), angle of arrival (AoA), and RSS (RSSI). The first two metrics demand time synchronization among beacons and target devices, while AoA-based method requires cumbersome antenna arrays. Compared with these competitors, RSS-based system has significant advantages: (1) WLANs are deployed almost everywhere; (2) RSS measurements are readily available in most RF chips; and (3) the localization algorithms have very low complexity.

In 2000, the first fingerprint-based localization system named as RADAR was developed by Microsoft Research Asia (Bahl and Padmanabhan 2000), as shown in Fig. 1. In RADAR, some reference points are chosen across the area of interest. On every reference point, an RF device is employed to measure the RSS values from different beacons. These RSS vector is recorded in a database with the corresponding coordinate of the reference point. In other words, every coordinate corresponds to a RSS vector. This vector is unique for every coordinate and thus is also referred to as fingerprint of that spot. When a target device is located in the area of interest, it will first measure the RSS vector in its communication range and then compare this vector with those in the radio map. After finding the RSS vector with the least Euclidean distance, the corresponding coordinate is chosen as the localization result. This algorithm is often referred to as the nearest neighbor (NN) algorithm. The intuitive idea behind this method is that if two positions are physically closer, their RSS vectors should have smaller Euclidean distance. This is not always the case, but it is statistically correct.

In 2001, the authors proposed another Wi-Fi location service that uses Bayesian networks to infer the location of a device, called Nibble (Castro et al. 2001). In the radio map, the joint distribution of RSS values from different beacons at a specific point is recorded as an entry. Then, during online phase, the likelihood probabilities of the received RSS vector conditioned on the assumption that the target is located on reference points are calculated and compared. Then, the reference points with largest probabilities are

Fingerprinting Localization, Fig. 1 A typical fingerprinting-based localization system contains online and offline phases

assumed to be neighbors of the target, and the target's location is the weighted average of the neighbors. The intuitive idea is that if the target is close to a specific reference point, their RSS vectors should be similar, and the corresponding probability should be large.

Since RADAR and Nibble, many other fingerprinting-based localization systems and techniques have been developed, and most of them are variants of either RADAR or Nibble. Compared with their ancestors, the variants are adjusted for specific scenarios to achieve better accuracy and efficiency.

Foundations

There are generally two metrics, the Euclidean distance and maximum likelihood ratio estimation. For the first metric, the Euclidean distance between the real-time RSS vector and those in the radio map needs to be calculated. Apart from Euclidean distance, probability can also be employed for localization (Castro et al. 2001). In training phase, the empirical distribution of RSS

vectors is obtained by measurements. During offline phase, the likelihood probabilities of different positions will be calculated. The larger the probability is, the closer the physical distance between the target and the reference point will be.

For both metrics, NN and k -NN algorithms can be employed for final localization. The k -NN algorithm provides a weighted result of the k nearest neighbors in terms of Euclidean distance or probability. The weights can be normalized reciprocal of Euclidean distance or the probabilities.

In spite of various strong aspects of the fingerprint-based localization techniques, it still has several major drawbacks in practical applications, and possible solutions have been proposed.

The first problem is the significant labor work coming with the construction of the radio map. As a matter of fact, the density of reference points is important for localization accuracy. However, to obtain and maintain a high-resolution radio map is not easy. To be specific, the typical density of radio maps in indoor environments is

1 point per square meter and 100 samples per testing point, so as to average out the fluctuations in RSS measurements. Besides, the radio maps require constant update due to indoor environment change. There are several possible ways to solve this problem. The first strategy is to only sample RSS vectors on a portion of reference points and estimate the RSS vectors on other points based on radio propagation model. This strategy was employed by RADAR, and the radio propagation model was discussed in many literatures (Seidel and Rappaport 1992; Han et al. 2015). The second strategy is to employ robots to do the labor work. These two strategies both show promising results in certain environments, but their applications to complex indoor environments are quite limited.

The second problem is how to effectively find the nearest neighbor or neighbors in large radio maps. For real-time localization, the delay introduced by searching radio maps can be quite significant. One possible solution is to divide the entries in the radio map into clusters (Youssef et al. 2003). Intuitively, when reference points are close, their RSS vectors should have similar characteristics.

The last problem is often referred to as device diversity or device heterogeneity. To be specific, the RF chip of the target device generally is generally different from that used for radio map construction during offline phase. For the same received signal, different RF chips may report different RSS (RSSI) measurements. Therefore, we cannot just use Euclidean distance to compare the similarity of two RSS vectors. As alternatives, cosine similarity (He and Chan 2014) and Tanimoto similarity (Jiang et al. 2012) are better choices, and they have been implemented in practical applications and results are reported.

Key Applications

Fingerprint localization techniques can be employed for positioning in ad hoc networks in various environments.

Definitions

5G wireless is the fifth generation cellular mobile technology based on specifications defined in Release 15 of 3GPP standards [1][2][3][4][5].

Historical Background

5G wireless is fundamentally transforming a radio network from pure wireless connectivity to the network for services. Mobile wireless access technologies have gone through several generations of evolutions to increase radio access capacity. The spectral efficiency has approaching Shannon capacity. However, there is enormous opportunity on support of various services. 5G wireless (3GPP TS 38.201-36.215 2017; 3G3GPP TR 38.801 2017; 3GPP TR 38.802 2017; 3GPP TR 38.803 2017; 3GPP TR 38.804 2017) is expected to support a variety of services more efficiently.

5G applications can range from Gigabit Society with personalized ultra-broadband TV and smartphone to autonomous car, connected home and cities, as well as remote sensors for agriculture and smart utility grid. It will dramatically improve our daily life. One example is healthcare. It could shift from curing to prevention. An ambulance could stop by your side at the moment you have a stroke or life-threatening event. Verizon *State of the IoT Market 2017* report has confirmed the double digital growth and expected game change from 5G services (Verizon 2017; Yang et al. 2016).

5G wireless will enable new services and applications, in particular, enhanced mobile broadband (eMBB), massive machine-type communications (mMTC), and ultra-reliable low-latency communications (URLLC). Figure 1 illustrated a service-based radio access architecture. The network is centrally controlled by an end-to-end self-organizing network (SON) with software-defined networking (SDN) in a virtualized radio access network (vRAN) and network function virtualization (NFV) environment.

This network transformation can support network slicing and differentiate services at access and transport nodes to ensure end-to-end performance, enabling fast service delivery. It gives us the ability to steer traffic in fine granularity to enforce policy-based routing and meet end-to-end Quality of Service (QoS) requirements of various applications.

5G wireless consists of an evolution of today's 4G LTE (Long-Term Evolution) network as well as a new standardized radio access technology known as 5G New Radio (NR). The first standardization phase of NR is expected to be completed in 2018, with a sequence of releases following after. 5G wireless brings us opportunities for more innovative services and revenue streams and also more challenges to support those services efficiently and reliably.

Spectrum Management

5G wireless demands large bandwidth to achieve the gigabit per second (Gbps) user data rate. 5G NR can operate in the frequency ranging from hundreds of MHz to 100 GHz with paired and unpaired spectrum at more than 100 MHz bandwidth to achieve 10 Gbps targeted peak data rate. Field trials for 5G NR critical technologies are conducted at 4 GHz, as well as 27 GHz and 37 GHz. Thus, spectrum and resource management are extremely important.

The low-band in sub-6 GHz can be utilized for wide area services, while high-band for ultra-dense small cells or fixed wireless applications. 5G wireless needs to support licensed spectrum

5G Wireless, Fig. 1 Radio access network to support various services

F

and leverage unlicensed and shared spectrum to increase throughputs and complement user performance.

Millimeter wave (mmWave) with extensive hundreds of MHz is critical for average user throughput larger than 1 Gbps in a loaded dense network with cell radius less than 100 m. mmWave and relies on massive MIMO (multiple inputs multiple outputs) to mitigate sensitivity to rain and fogs. Massive antenna system can form and track user-specific narrow beam to ensure service quality and reliability. This can mitigate a relatively large propagation loss and recover from blockages.

Dual connectivity will gracefully extend initial 5G to existing LTE wide area coverage. 5G could use licensed assisted access scheme similar to LTE to leverage more than 500 MHz unlicensed spectrum under 6 GHz and even more in mmWave.

Idle and connected mode mobility management is essential to ensure consistent user experience across the network. Those are challenging in a heterogeneous network with large range of inter-site distances and frequency bands. NR supports mobility without reconfiguration and make-before-break handover with multiple connections. Thus NR reduces the handover interruption time to zero from current LTE's minimal 25 ms.

5G will bring in more flexibility on frequency and time allocation and allow flexible uplink and downlink multiplex to improve spectrum utilization. The 5G NR in Rel.15 will support more flexible Time Division Duplex (TDD) resource

allocations; hence each user can have individually specified downlink and uplink time slots. In later releases, we are expecting even more flexible full dynamic Frequency Division Duplex (FDD) and TDD allocation, as well as full duplex radios to improve Integrated Access Backhaul.

Fundamental of 5G Wireless

5G NR specification is still under development in 3GPP (3GPP TS 38.201-36.215 2017). The technical studies (3G3GPP TR 38.801 2017; 3GPP TR 38.802 2017; 3GPP TR 38.803 2017; 3GPP TR 38.804 2017; Ericsson 2017) completed in March 2017 have summarized very well the agreed NR framework. In this section, we will provide high-level agreement of 5G wireless from access scheme, massive MIMO, and signaling aspects.

Access Scheme

5G NR has a dynamic frame structure with flexible numerology that is scalable for a wide range of spectrums and applications. The key components consist of waveform, frame structure, modulation, and coding schemes.

5G NR waveform is Orthogonal Frequency Division Multiplexing (OFDM) with a cyclic prefix (CP) in both downlink and uplink up to at least 52.6 GHz. The same waveform on downlink and uplink has simplified the overall design, in particular, inclusive of wireless backhauling, device-to-device, and vehicle-to-X applications. Additionally, discrete Fourier transform spread OFDM

5G Wireless, Fig. 2 Flexible and scalable resource allocation

(DFT-s-OFDM) is also supported in uplink to match LTE coverage. Windowing or filtering can be applied on top of OFDM to improve spectrum confinement and enable spectrum utilization higher than 90% of current LTE.

The 5G NR subcarrier spacing, Transmission Time Interval (TTI), and cyclic prefix are flexible and configurable based on deployed spectrum and service requirement, as shown in Fig. 2. The subcarrier spacing can be 15×2^k extended from fixed 15 kHz in 4G LTE, while k is an integer. Thus it supports ultra-wide band for the Gbps enhanced broadband service and fixed wireless communications. It will allow a shorter time slot and larger subcarrier spacing for a delay-sensitive mission critical application with a finer time granularity. It also allows a narrow bandwidth and smaller subcarrier spacing for massive IoT connections to extend coverage and reduce device complexity and power consumption.

The NR frame structure supports a self-contained transmission; thus the reference signals required for data demodulation are included in the given slot or beam. It also supports well-confined transmissions in time and frequency, avoiding control channels mapping across full system bandwidth. It avoids static timing relation across slots and different transmission directions and removes the resource allocation limitation of predefined transmission time.

NR supports the same modulation schemes as that of LTE, which includes QPSK, 16-QAM, 64-QAM, and 256-QAM. It supports $\pi/4$ -BPSK

for DFT-s-OFDM for extended coverage. It will define 1024-QAM for fixed wireless applications. The final NR specification will cover a more extensive modulation scheme with different user equipment (UE) categories for diverse use cases.

NR supports low-density parity-check (LDPC) codes for the data channel and polar codes for the control channel. Those have evolved from traditional convolutional and turbo codes used in LTE. The LDPC has showed much superior performance at a wide range of coding rates. It supports high peak rate and low latency at high coding rate and high coding gain with high reliability at low coding rate. Polar codes are the first class of codes shown to achieve the Shannon capacity. It will be used for Physical Broadcast Channel (PBCH) and control information with shorter block length at a reasonable decoding complexity.

Massive MIMO

The massive MIMO provides a means to support high reliable services and achieve the three times spectral efficiency enhancement required by IMT-2020. NR beamforming can be applied to both data transmissions and initial access.

NR will define various antenna solutions depending on spectrum. For sub-6 GHz, most likely up to 32 transmitter chains with FDD spectrum are used. The spectral efficiency is improved by high-resolution channel state information (CSI) reporting and multiuser MIMO (MU-MIMO). For higher frequencies, a larger number of antenna (>128) can be supported in a given aperture. TDD spectrum- and reciprocity-based schemes are assumed. mmWave with an analog beamforming is typically limited to a single beam per slot per radio chain and thus requires beamforming on both transmitter and receiver. To support those diverse user cases across 100 GHz, NR defined a highly flexible and unified CSI framework to reduce the coupling among CSI measurement, CSI reporting, and the actual downlink transmissions. This framework also supports multipoint transmissions and coordination. The self-contained frame structure allows network to seamlessly change the transmission point or beam as devices moving across radio nodes.

5G Wireless, Fig. 3 Massive MIMO and benefit

Full-dimension MIMO (FD-MIMO) can significantly increase capacity and coverage and improve reliability and network resiliency, on both horizontal and vertical domains. As we can see from Fig. 3, the more antenna branches, the less fading margin required to meet a reliability requirement. For example, only 3 dB fading margin is required for 16 antennas at 99.99% reliability, while 20 dB margin required for 2 branches and 40 dB required for single branch to achieve the same reliability. It is almost impossible to achieve 5 nine reliability in a fading channel with single branch antenna, while only require 5 dB margin for a 16-branch receiver.

Massive MIMO also brings challenges as the beamforming algorithms are complicated. The device and eNB complexity does not scale well with the number of increased antenna elements. RF and baseband design for massive MIMO at network, as well as at user equipment, are still at development stages. Mobility and connectivity over very narrow beams require fast tracking and switching. Front-haul bandwidth in tens of Gbps is required for the Gbps data transmission among radio, baseband, and network. Thus a lower-layer splitting with compression is necessary to enable advanced receiver at base station while maintaining reasonable front-haul throughput and latency requirement. The standardized lower-layer split-

ting will enable operator to mix and match radio units and base station processors from different vendors.

Dynamical antenna array configurations with flexible number of beams on vertical and horizontal planes are required to support various deployments as showed in Fig. 3. Simulations in 3GPP have shown that for a dense urban skyscraper with vertical traffic distribution, the vertical dominant antenna ports provided more gain, while for typical suburban low-rise deployment, more horizontal ports will provide high capacity. Those will serve as a stepping stone toward 5G by gradually increasing the number of antenna ports from current 4 to more than 32 transmission ports. This will prepare us for 5G massive number of antenna ports.

Reference Signals and Signaling Efficiency

5G NR has much lean reference signals and signaling overhead that translates directly to a better spectral efficient. The always-on broadcast signals are minimized. Common reference signals are replaced by UE-specific reference signals with improved feedback accuracy and less overhead.

The four main reference signals in NR are demodulation reference signal (DM-RS), phase-tracking reference signal (PTRS), sounding

reference signal (SRS), and channel state information reference signal (CSI-RS). DM-RS is used to estimate the radio channel for demodulation. It is UE-specific, only transmitted on an as-needed basis, for example, the transmit interval could be long for low-speed user, while short for high-speed mobile users. PTRS is introduced to compensate UE-specific oscillator phase noise for mmWave. The SRS on uplink and CSI-RS on downlink are used to conduct CSI measurement for a scheduler and link adaptation. They will also be utilized for massive MIMO precoder design and beam management on uplink and downlink, respectively. It is expected 5G NR will improve spectral efficiency by at least 10% from those UE-specific reference signals.

5G NR also reduces signaling overhead by introducing a new RRC inactive state. Thus it can save control signaling by 15% and decrease signaling latency. It also replaces the always-on broadcast signals with on-demand system information.

This reduced signaling increases the system stability, particularly in an overloaded scenario (Yang et al. 2016). Thus, 5G NR is a more efficient, reliable, and robust communication means.

One Network for a Variety of Services

One operational network is a cost-efficient way to engineer, maintain, and operate radio networks from the perspective of capital and operational expense. The 5G wireless network can be used for eMBB, mMTC, and URLLC applications in a wide area radio access, D2D, V2X, and wireless backhaul use cases.

Wireless networks are evolved toward both centralized resource sharing and distributed edge mobile computing. Artificial intelligence is introduced to enable self-organizing at radio accesses, software-defined networking, and network function virtualization at core networks to allow the network to be more dynamic and intelligent with service and content awareness.

5G wireless will be a combination of evolved LTE network with new radio access technologies targeting for wide bandwidth, expanded spec-

trum, enhanced mobile broadband, as well as mission critical connections. This access network with intelligence at both edge and cloud can serve entire communities and industries, supporting both Gigabit Society and the Internet of Everything.

Key Applications

5G wireless will support varieties of applications from ultra-broadband services, to mission critical applications, as well as massive Internet of Things. It will support above 100 MHz instantaneous bandwidth from hundreds of MHz to GHz radio frequency ranges. 5G will profoundly enrich our daily life.

Synonyms

Flow table exhaustion attacks; Flow table overload attacks

Definition

Flow table overflow attacks consume flow tables that forward and process packets of flows in software-defined networking (SDN), which results in no space left for other flows to install flow rules and thus incur network denial-of-service (DoS). Such attacks are serious security threats in SDN, as they can be easily launched by an adversary having or compromising hosts in the target network.

Historical Background

The flow table overflow attack is a kind of table overflow attacks. Table overflow attacks have existed for decades after the Internet was born in 1969. The most common table overflow attack in legacy computer networks is the MAC address table overflow attack. Such an attack is launched by an adversary that sends lots of packets spoofing source MAC addresses to a switch, and thus the switch MAC address table is fully loaded. Another similar attack is the routing table overflow attack. In such an attack, an adversarial

router advertises routes to nonexistent destinations to authorized routers, which can saturate the routing table.

Flow table overflow attacks was newly discovered after the first software-defined networking (SDN) standard, i.e., OpenFlow (McKeown et al. 2008), was announced in 2008. Later on in 2013, studies Kreutz et al. (2013) and Kloti et al. (2013) showed concerns on flow table overflow attacks that can disrupt SDN. In particular, Shin and Gu (2013) designed and evaluated the first feasible flow table overflow attack in SDN, i.e., SDN Scanner, which can fingerprint SDN networks and then generate packets with random header fields to exhaust flow tables. In 2017, Pascoal et al. (2017) improved the attack so that it can be launched with low-rate traffic. At the same time, Cao et al. (2017) provided the LOFT attack, which is sophisticated and can exhaust flow table with a minimal rate in a stealthy way.

Foundations

Flow table attacks are serious security threats in SDN. To understand the attacks, the necessary context should be explained. Hence, a brief introduction to SDN must be firstly noted. SDN is an emerging network paradigm, which decouples the control plane from the data plane. The control plane consists of a centralized controller responsible for taking over the whole network. The data plane contains SDN switches that forward packets. The flow table in SDN switches plays a key role on supporting SDN abstraction, as almost all decisions made by the controller, e.g., how to route flows, are translated into flow rules in the flow table. To support line-speed forwarding and flexible packet processing, dedicated memories called ternary content-addressable memory (TCAM) are used to form the flow table. However, such memories are power-hungry and expensive. Currently, most commercial hardware switches can only store a limited number of flow rules in TCAM (typically, 1500 to 3000 rules (Pascoal et al. 2017)), which has potential risk to be overflowed. Moreover, some network applications in the SDN controller adapt fine-

Flow Table Overflow Attacks, Fig. 1 The proactive rule installation mechanism in SDN

grained control. For example, a firewall application may install flow rules according to IP addresses and TCP ports to block or allow some specific flows. Such kind of application exacerbates the potential risk of flow table overflow.

On the other hand, the proactive rule installation mechanism in SDN can be easily leveraged by an adversary to overflow the flow table. Figure 1 illustrates the mechanism. When a packet from a flow arrives at the ingress switch, it will be forwarded and processed by the related flow rules. If no rule matches the packet, a packet-in message generated by the switch will be reported to the controller for querying flow rules. In normal cases, new flow rules will be directly installed into the switch. However, when the flow table has no free space, the flow rule will be rejected by the switch or installed at the expense of deleting an existing flow rule, which depends on the behavior of switches. Either behavior can degrade the throughput of flows when the flow table is overflowed and thus incurs network DoS. Typically, there are three types of attacks that leverage the above mechanism to overflow flow table:

- *Brute-force flow table overflow.* In such an attack, a compromised host in the target network generates a huge number of anomalous packets. The header fields of each packet are

spoofed as random values. Thus, such packets have high probability of matching no flow rules, which means many new flow rules will be installed into switches. Consequently, the flow table of switches can be quickly saturated.

- *Slow flow table overflow.* The attack is an improvement of the brute-force attack. The brute-force attack needs to generate a huge number of anomalous packets with a high rate. In order to decrease the attack rate, the attack assumes that an adversary controls many hosts in a botnet so that each host can send a unique flow to a common destination. Hence, to route these unique flows, two flow rules (incoming and outgoing rules) for each unique flow will be installed into each switch along with the routing path. To make the attack successfully overflow flow table, it requires the number of the compromised hosts is bigger than half of the number of flow rules that a switch can support.
- *Sophisticated flow table overflow.* The sophisticated attack overflows flow table with a minimal rate in a stealthy way. It contains two phases: probing and attacking. In the probing phase, it generates probing packets to infer the controller's logic of installing flow rules and the survival time of each installed rules. In the attacking phase, a compromised host generates packets to stealthily overflow flow table. Such packets are carefully crafted according to the previously inferred controller's logic of installing rules so that each packet can trigger a new rule installation. Moreover, the minimal packet rate of keeping flow tables overflowed over time are also calculated based on the survival time of flow rules. Thus, packets are sent in a way where flow tables can be slowly overflowed with a minimal attack rate.

Key Applications

Overflowing flow tables can be used as a method to disrupt the target SDN and incur network DoS.

Definitions

Fog computing is an extension of the cloud computing paradigm from the core of the network to the edge of the network. It is an architecture that utilizes collaborative resource-limited devices (e.g., mobile end-devices, access points, routers, switches) or more capable machines (e.g., cloudlets) at the near-user edge to provide storage, communication, and computing resource for services and applications to users.

Historical Background

In the past years, computing paradigms have evolved from distributed and parallel to cloud computing, which can provide elastic resources to applications on the resource-limited end-devices. However, the connection between the cloud and end-devices over the Internet is not suitable for latency-sensitive applications, such as wearable computing, smart metering, smart home/city, vehicles, and health monitoring. That

is because existing communication systems cannot meet the ultralow latency requirements. For example, LTE can achieve a typical round-trip latency of 25 ms, while many ultralow-latency applications require less than 10 ms of latency. Thus, although, nowadays, cloud computing is widely used, many challenges remain unsolved, such as mobility support, location awareness, and ultralow latency requirements.

Fog computing is then proposed by Cisco (Bonomi et al. 2012) in 2012 to overcome those challenges by migrating the computing from the cloud to the edge of the network. It enables computing and supports service virtualization at the edge of the network, closer to the end-devices of users. On the other hand, in 2014, the work (Chiang 2014) from Princeton University proposes *fog network* as a similar concept of the fog computing while focusing more on utilizing one or many end-user clients or near-user edge devices to handle storage, communications, control, configuration, measurement, and management function of the IoT collaboratively. Meanwhile, *Fog-Radio Access Network (F-RAN)* was introduced at the Next Generation Mobile Network (NGMN) Forum in 2014 (Shih et al. 2017). The F-RAN leverages the equipment in the radio access network (RAN) on small cells to be aggregators connecting the IoT devices and the cellular network. Moreover, many standardization organizations, such as European Telecommunications Standards Institute (ETSI), and research projects, such as a European Union project named “Distributed Computing, Storage, and Radio Resource Allocation over Cooperative Femtocells (TROPIC),” also focus on the idea of “extension of computation to the edge of the network.” To consolidate those efforts on developing fog computing, in 2015, OpenFog Consortium was founded by ARM Holdings, Cisco Systems, Dell, Intel, Microsoft, and Princeton University to promote interests and development in fog computing. OpenFog particularly emphasizes the openness and hierarchy where implementations of the fog computing architecture can reside in multiple layers of a network’s topology.

There are similar concepts such as Mobile Cloud Computing (MCC) (Dinh et al. 2013) and Multi-Access Edge Computing (MEC) (Taleb et al. 2017). MCC moves the data storage and processing from mobile devices to more powerful devices, while MEC focuses on deploying resource-rich fog servers like cloudlets at the edge of mobile networks. MEC was initiated in 2014 by ETSI under the name of Mobile Edge Computing; then its scope has been expanded in 2017 to encompass nonmobile network requirement and replace the Mobile with Multi-Access in the name. On the other hand, fog computing is a more generalized computing paradigm such that the computation is performed at the edge of the network, but it is not defined who exactly performs the computing.

Foundations

Architecture of Fog Computing

A typical architecture of the fog computing composed of the access network and end-devices of users. There are radio access equipments, such as Wi-Fi access points or femtocell base stations and remote radio heads (RRHs) extended from existing macro-eNodeBs, at the access network, serving as the middle layer between the end-device and the cloud. Those equipments can communicate with each other directly via advanced wireless technologies, and they are all connected to the core network and the Internet via the back-bone links. The end-devices of users (such as set-top boxes, network-attached storage, wearable devices, smartphones, or IoT smart devices) are connected to the access points or base stations via wireless technologies. The cloud behind the core network can provide non-real-time computing and big data analysis as the fog is considered as an extension, not a replacement, of the cloud.

To provide Quality-of-Service (QoS) and enable flexible operation, fog computing has many flexible and scalable options for computing resource deployment. The computing resources can be provided by every role in the network. That includes the existing radio access equipments and extra dedicated servers (e.g.,

cloudlet) deployed beside those equipments at the access network. In addition, users can also provide the sparse computing resource of their end-devices. Those devices, which are the basic units to provide computing resource, are denoted as fog computing nodes (FNs). Also, there exists the fog controller, which can be any FNs or independent servers in a centralized or distributed fashion, which is mainly in charge of receiving service requests, distributing tasks to FNs, and summarizing processing results.

A typical IoT application service model of the fog computing is that, first, the IoT device initiates the service request to the fog controller and, then, the fog controller distributes the computing-intensive tasks of the service to one or multiple FNs. The FNs process those tasks and return the outcomes to the fog controller. Finally, the controller summarizes the received outcomes and then sends the final outcomes back to the IoT device.

Collaboration Between Fog and Cloud

Fog computing can be collaborated with cloud computing such that FNs might be integrated with cloud computing infrastructure and IoT devices. Some computing tasks will be carried locally at IoT devices; meanwhile, some computing tasks will be served by FNs, and some might be forwarded to cloud computing infrastructure. We call the system with IoT devices, fog nodes, and cloud computing as a Thing-Fog-Cloud continuum. The computational tasks could be divided and distributed in this Thing-Fog-Cloud continuum. Depending on the computational loading, networking congestion, and application requirements, the computing tasks might be allocated to suitable nodes in this Thing-Fog-Cloud continuum.

Meanwhile, there are diverse IoT applications with various delay requirements served by the common infrastructure. There will be delay-tolerant and delay-sensitive IoT applications coexisting in the wireless fog computing environment. For example, in the fog-enabled factory automation environment, robotic control IoT application is delay sensitive, while collecting manufacturing parameters for IoT process

enhancement is delay tolerant. With the mixed delay-sensitive and delay-tolerant data packets, networking infrastructure needs to be able to differentiate those packets and prioritize their transmission. Besides, computational resource allocation framework should also differentiate the serving policies for delay-tolerant and delay-sensitive tasks. The differentiation and management mechanism might be implemented in IoT device level or in fog nodes. For example, a fire alarm or pressure alarm sensor might be treated differently than a weight sensor that measures the weight for a box of products. In another example, a fog node that receives videos from a surveillance camera might be triggered to transmit a delay-sensitive or a delay-tolerant message, based on the video recognition results from the received surveillance videos. In addition, the delay-sensitive emergency videos might need to be further analyzed with high priority in a fog node; meanwhile, the non-emergency video clips could be forwarded to cloud computing infrastructure to be stored for record or for future analysis. With the flexible management and orchestration in the fog computing system, intelligent IoT applications could be served (Ku et al. 2017).

Enabling Technologies of Fog Computing

Fog computing also relies on some enabling technologies that allow flexibility and multi-tenancy support:

- *Virtualization:* Virtualization in computing infrastructure and networking systems has been observed as an emerging trend. More and more network infrastructure nodes might be implemented with general-purpose hardware and achieve adaptive configurability through software. With this trend, fog computing technologies might become possible by utilizing those general-purpose hardware platforms. Classic virtualization technology, virtual machine (VM), consumes a significant amount of resources and has slow startup process because it needs to boot a complete OS. Different from the traditional VM,

the emerging container technology, whose abstraction takes place at the OS level, is a lightweight virtualization solution that enables portable runtimes of fog services, which is particularly useful for mobile users (Xavier et al. 2013).

- *Network Function Virtualization (NFV)*: NFV is a technology that enables decoupling network functions and services from proprietary hardware (Han et al. 2015). With NFV, hardware node could be used to provide networking functionality in software as well as fog computing services. Also, fog computing can also leverage NFV for managing the virtualized instances related to specific applications and services. For example, increasing the resources for a popular service can be easily achieved by adding another software instance or particular resources, e.g., computing power, storage, or network bandwidth.
- *Software-Defined Networks (SDN)*: SDN is a technology that decouples the control plane from the data plane and enables network programmability through the use of standard APIs (Kreutz et al. 2015). SDN introduces a logically centralized control, abstracting the underlying network infrastructure, and enables real-time network control. With SDN, fog controller can have flexible and efficient management for data routing.

Key Applications

Fog computing paradigm and its integration with wireless networks are aimed to provide low-latency IoT services. By placing computing resources that are close to IoT devices, some delay those fog computing nodes that could serve sensitive computing tasks. The following are some key applications of fog computing:

- *Mobile augmented reality*: Due to the widespread availability, portability, and built-in good-quality cameras of smartphones, mobile augmented reality (mobile AR) has been drawing many attentions. Mobile AR,

enabling virtual graphic imagery to overlay physical object in real time, makes many new applications (e.g., navigation, public security, real-time translation) possible. Some popular products or projects include Google Glass and Microsoft HoloLens that have been introduced. One of the core components for mobile AR is the pose tracking module, in charge of calculating the relative pose of the camera in real time for the location and orientation of the virtual components. Typical CPU hardware on smartphones is not able to carry the computational complexity of tracking algorithm; thus, the fog computing can provide the necessary application-layer computing power via distributing the computing-intensive tasks of the mobile AR to multiple FNs (Pang et al. 2017).

- *Traffic control system*: A smart traffic control system enables traffic signals to adapt to actual traffic demand. The system needs very fast interactions such that traffic lights can respond to the fast-changing traffic conditions and accident-avoidance alerts can be given promptly. Fog computing can provide near-edge computing power to those traffic lights and roadside sensors for the ultralow-latency decision-making (Liu et al. 2018).
- *Content caching*: In fog computing system, caching mechanism is also considered as a useful design for latency reduction, especially for the application for information query and downloading (Tandon and Simeone 2016). One such application is a video surveillance system that recognizes the people entering a building through video matching with the personal database. As people go to their office area daily, caching mechanism in a local fog node will be helpful for pattern matching and basic information query in the nearby area.
- *Autonomous and connected cars*: With the emerging trend of autonomous driving and advancement of vehicular communication technologies, IoV (Internet of Vehicles) becomes an important IoT deployment scenario (Kaiwartya et al. 2016). Many applications for IoV (e.g., augmented reality for information providing through a heads-up

display and accident avoidance in autopilot) not only need the near-real-time response but also require a tremendous amount of computing power to process a significant amount of data generated by the sensors on the vehicles. Thus, fog computing might play a vital role in the IoV deployment via moving the intelligence closer to the vehicles, as many IoV applications are delay sensitive. In the future, some vehicles might be equipped with powerful computing hardware, such as GPU or FPGA, and some vehicles might only have limited computing power. Fog computing can be a suitable solution for enhancing computational capabilities in vehicular environments via moving the intelligence closer to the vehicles. To provide low-latency IoV services, some roadside units might also be capable of serving as a fog computing node, and some cellular base stations might be tightly integrated with fog servers in the radio access network or in the core network. V2X (Vehicle-to-Everything) communications might need to be tightly integrated with fog computing resource in this scenarios.

- *Wearable application and service offloading:* Wearable devices have become ubiquitous and provide convenient features for users, such as heart rate monitor and fitness tracker. However, since those devices are designed to be lightweight and power-saving, the computing capability of wearable devices is often limited. The existing solution is to pair with the local hub, mostly smartphone, via Bluetooth Low Energy (BLE) or Wi-Fi interface. Whenever a request takes place, the wearable device will automatically transfer it to the local hub and then reply with the results. Connection via Bluetooth, however, is only functional within a narrow connection range, whereas connection via Wi-Fi interface has a long response time. It means when someone left the smartphone at home and walked out with the wearable device only, the services may suffer from prolonged network latency delay. Fog computing can be helpful to address those shortcomings via deploying the wearable services at the

edge side to serve the wearable devices (Lin et al. 2016).

- *Tactile Internet:* The Tactile Internet requires ultra-responsive and ultrareliable network connectivity that enables it to deliver physical haptic experiences remotely (Simsek et al. 2016). The concept of Tactile Internet gives us a sneak preview into many future promising applications, such as exoskeletons, remote surgery, virtual sport training, and remote robot controlling.

Future Directions

As fog computing is still in its infant stage, most future needs and challenges will come in the areas of fog computing. Listed below are some future challenges:

- *Joint networking, storage, and computing resource allocation:* Close integration between wireless networking infrastructure and fog computing will reduce the overall end-to-end latency for real-time IoT applications. As a result, joint resource allocation for wireless radio resource and computing resource is critical to meet the low latency requirements for delay-sensitive IoT applications. For example, to minimize the end-to-end application latency, assigning a computing task to the nearest fog node might not be optimal. The optimal computing task assignment mechanism might consider the wireless channel quality to a certain base station or access point, network latency in wired-line backhaul link, and computing load in a fog node. Moreover, when caching mechanism is applied, fog storage needs to be considered in resource allocation and management, in addition to computing and wireless network resource allocation.
- *Platform management and orchestration mechanism:* Between IoT devices and cloud computing servers, there might be possibly multiple tiers of fog nodes. The computing tasks might be allocated through a multi-

tier fog hierarchy or offloading from a fog node to another peering fog node. Thus, in fog computing systems, management and orchestration mechanism is essential for the smooth operation of IoT applications with different requirements that coexist in the fog computing environment.

- *Mobility support:* Compared to factory automation applications, in which devices are mostly static, devices in vehicular IoT applications or wearable applications move with mobility. Those IoT devices might connect to their best-serving fog node at one moment that might become sub-optimal configuration as the vehicle or individual moves. As a result, the fog computing deployment needs to consider the mobility issue. In addition, mobility prediction and service provisioning might be included for better QoS of fog deployment.
- *Security and privacy:* Security and privacy are also important issues in the fog. Many security and privacy issues of the cloud are inherited in fog computing since the fog is considered as an extension of the cloud. Although some issues can be addressed using existing schemes, new security and privacy challenges arise due to the distinct characteristics of fog computing, such as mobility, heterogeneity, large-scale geo-distribution, location awareness, and ultralow latency. For example, how to design access control across client-fog-cloud with restriction is challenging. In addition, the location privacy of the FNs and the users is also a critical issue as task offloading takes place with consideration of their locations for lowering the latency.
- *Business model and incentive design:* Fog computing cannot be prosperous without a sustainable business model. The computing platform consists of the following three parties: (1) the operator, who owns the radio access equipment at the edge of the networks; (2) application service providers, who operate delay-sensitive applications; and (3) users who enjoy the applications. The operator can provide fog computing service to the delay-sensitive applications, run by the application

service providers, at near edge of the users via utilizing the computing resource of those radio access equipments. The business model needs to ensure every party can gain a positive benefit from joining the service. Two main issues of the model need to be resolved: first, the operator needs to know its cost, i.e., the amount of resource needed to fulfill the service requests of an application within a certain degree of latency. Second, the price of the service should be set as both operator and application service provider agree.

Definition

Frequency-domain equalization (FDE) is a technique to mitigate the intersymbol interference (ISI) associated with the channel

effects of the transmission medium, where the equalization is done through frequency-domain processing. The FDE is done digitally by using discrete-time Fourier transforms (DTFTs), which can be efficiently implemented by the fast Fourier transform (FFT) algorithm. For multicarrier (MC) modulations such as orthogonal frequency division multiplexing (OFDM), the FDE procedure occurs naturally, since the data are transmitted in parallel in the frequency-domain. However, FDEs can also be employed with single-carrier (SC) modulations and have been shown to be a great alternative to conventional, time-domain equalizers (TDEs). For this reason, single-carrier with frequency-domain equalization (SC-FDE) and OFDM are nowadays the most popular broadband transmission techniques.

Historical Background

The bit rates and bandwidth of wireless communication systems increased substantially over the last decades, making them an effective alternative to wired communications and allowing users to experience data rates on the order of many MBit/s or even GBit/s. The evolution of wireless communications is intimately related with the improvement of the transmission techniques that support them, which have become more resilient to the multipath propagation, as well as easily implemented in the digital domain through modern signal processing algorithms.

The transmission over frequency-selective channels such as the ones associated with multipath wireless scenarios leads to ISI and, consequently, performance degradation, leading to the need to employ equalizers. The optimum receiver under ISI conditions is the maximum likelihood sequence estimation (MLSE) receiver, also known as Viterbi equalizer, whose complexity grows exponentially with the channel impulse response length. Therefore, MSLE is only suitable for short impulse responses, since its complexity becomes prohibitively high for large constellations and/or channels

with long impulse response (Forney 1972). The conventional approach is to employ TDE schemes (Qureshi 1985), which although simpler than MSLE can still be too complex since they require highly complex filters, composed by a very large number of taps. Therefore, TDEs are not suitable for the highly frequency-selective scenarios that one might expect in broadband wireless systems.

Multicarrier transmission techniques, which were proposed in the mid-1960s (Chang 1966; Saltzberg 1967), but whose importance only started in the mid-1990s, with the strong evolution of electronics and digital signal processing techniques (DSP), are one of the solutions for wireless broadband communications. Among those techniques, the most popular is OFDM (Cimini 1985; Bingham 1990), which is a prefix-assisted block transmission scheme. The key advantage of OFDM schemes is the decomposition of a frequency-selective channel in a large number of parallel channels that behave as flat channels at the subcarrier level, simplifying the equalization procedure.

However, since OFDM signals are formed by a large number of modulated subcarriers, their envelope has substantial peak-to-average power ratio (PAPR), which constitutes a severe problem that can promote the unwanted effects of some radio frequency (RF) impairments, such as nonlinear distortion. In that context, SC-FDE modulation (Sari et al. 1994; Falconer 2002) was proposed as an alternative to OFDM, which can achieve similar performance without the problems associated with nonlinear distortion such as in-band radiation and out-of-band (OOB) radiation.

In the last decade, SC-FDE techniques have evolved, allowing performances close to the matched filter bound (MFB). The main enabler of such excellent performance is the concept of iterative block decision feedback equalization (IB-DFE) (Benvenuto and Tomasin 2002), where the equalization is done iteratively to further reduce the ISI levels and improve the performance.

Foundations

The impact of multipath channel on the transmitted signals can be modeled as a linear convolution. However, if the data is transmitted in blocks and a cyclic prefix (CP) longer than the overall channel impulse response (including transmit and receive filters) is appended to each block, then the linear channel convolution behaves as a cyclic convolution with respect to the useful part of the data block. In fact, by adding the CP, which essentially is a repetition of the last part of the data block, we have two main effects: (i) we are able to remove the interference between different blocks, and (ii) the useful part of the received signal (i.e., after removing the CP) is the useful part of the transmitted block times a circulant matrix. Since a circulant matrix can be diagonalized by a discrete Fourier transform (DFT) matrix, in practice this means that there will be no interference at the subcarrier level (or intercarrier interference (ICI)). Therefore, in the frequency-domain (i.e., after a DFT operation on the useful part of the received block), the output of a multipath channel can be seen as the subcarrier-wise multiplication of the channel frequency-response and the transmitted data. The FDE input for a given subcarrier k is given by

$$Y_k = H_k S_k + N_k, \quad (1)$$

where H_k , S_k , and N_k are the channel frequency-response, the data, and noise (assumed additive white Gaussian noise (AWGN)) components associated with the k th subcarrier, simplifying tremendously the channel equalization process, since the channel behaves as flat at the subcarrier level. Clearly, the use of a CP leads to lower energy and spectral efficiencies. However, the benefits of CP in terms of equalization simplicity and achievable performance are considerably higher. For single-carrier modulations, an inverse discrete Fourier transform (IDFT) brings FDE output (i.e., the equalized signal $\tilde{S}_k$) back to the time domain, where the detection is performed and an estimate of the transmitted symbol, $\hat{s}_n$, is obtained. A conventional FDE scenario is illus-

Frequency-Domain Equalization in OFDM and Single-Carrier Modulation, Fig. 1 Conventional FDE scheme

trated in Fig. 1. This FDE forms the essence of SC-FDE schemes, where a data block with an appropriate CP is transmitted and an FDE is adopted at the reception.

However, the FDE is not restricted to SC-FDE and is also at the core of the popular OFDM schemes. In fact, both OFDM and SC-FDE are CP-assisted block transmission techniques with an FDE at the receiver. Moreover, the overall implementation complexity of the two techniques is similar, since both have a pair of fast Fourier transforms (FFTs) (which implement the DFT/IDFT) in their communication chain. Their main difference relies on the fact that, in SC-FDE, both FFTs are placed at the receiver, while in OFDM, since the data is transmitted in the frequency-domain, there is no need to have an IDFT after the FDE. This explains why the reception is more complicated in SC-FDE than in OFDM and why SC-FDE signals can have much lower PAPR than OFDM signals. For this reason, SC-FDE is usually employed in uplink, while OFDM is more adequate for downlink communications, where the energy efficiency requirements are lower. The communication chains of SC-FDE and OFDM are shown in Fig. 2. After the FDE, the equalized signal is sent to the detector that outputs the estimated data signal $\hat{S}_k$ or $\hat{s}_n$ when OFDM or SC-FDE is considered, respectively.

The basic FDE can be regarded as a linear equalizer operating at the subcarrier level. This is suitable for OFDM schemes, where the data symbols are directly transmitted by the subcarriers.

For SC-FDE schemes, the FDE is usually optimized under the minimum mean squared error (MMSE) criteria (Rugini et al. 2005; Pincaldi et al. 2008), which means that there will be some

Frequency-Domain Equalization in OFDM and Single-Carrier Modulation, Fig. 2 Simplified communication chains of OFDM (top figure) and SC-FDE (bottom figure)

Frequency-Domain Equalization in OFDM and Single-Carrier Modulation, Fig. 3 Conventional nonlinear FDE scheme

residual ISI. It is well-known that for SC modulations, nonlinear equalizers outperform linear equalizers, the same applying to SC-FDE. Therefore, it is desirable to have nonlinear FDEs, and several approaches have been proposed to achieve this. The most popular nonlinear FDE is the IB-DFE (Benvenuto et al. 2010), where we have a feedforward part characterized by the coefficients F_k (as with linear FDEs) and feedback part characterized by the coefficients B_k . The general scheme of nonlinear FDEs is represented in Fig. 3. An MMSE-based IB-DFE is characterized by

$$B_k^{(l)} = F_k^{(l)} H_k - 1. \quad (3)$$

Therefore, for IB-DFE techniques, the equalized signal associated with a given subcarrier is given by

$$S_k^{(l)} = F_k^{(l)} Y_k - B_k^{(l)} \hat{S}_k^{(l-1)}. \quad (4)$$

As we increase the number of iterations of the IB-DFE, the residual ISI levels at the FDE output are reduced, which allows performance improvements as we increase the number of iterations, at the expense of some additional and usually affordable computational complexity.

$$F_k^{(l)} = \frac{H_k^*}{(1 - |\rho^{(l)}|^2) |H_k|^2 + \frac{1}{\text{SNR}}}, \quad (2)$$

where $\rho^{(l)}$ is the reliability of the data block detected in the l th iteration, which can be computed as described in Silva et al. (2012), and SNR is the channel's signal-to-noise ratio. The feedback equalization factor is given by

Key Applications

The FDE concept can be used in OFDM and SC-FDE, as well as other block transmission techniques like multicarrier code division multiple access (MC-CDMA) and direct sequence code division multiple access (DS-CDMA), both in

single-antenna and multi-antenna scenarios like multi-input, multi-output (MIMO) schemes.

OFDM and SC-FDE are employed in the physical layer of several systems such as WiMAX (WiM 2004), 4G cellular systems (LTE 2006), and digital television broadcasting (DVB 2009). Moreover, they are the main contenders for the radio access of several 5G use cases.

Definition

A wireless relay system involves at least three nodes: a source node, a relay node, and a destination node. The relay node assists the transmission of information from the source to the destination. The relay channels include all channels between these nodes.

Historical Background

Due to the complicated transmission media, fading has been considered as a key characteris-

tic feature of the wireless communications. As the wireless fading greatly shortens the delivery distance, the main task in wireless communication systems is to combat the fading to achieve reliable communication. To address this issue, a number of transmission techniques have been proposed. Among them, wireless (radio frequency) relays are widely known to be useful for combating radio channel fading over long distances. Relay technique is a promising technique since it allows a highly flexible equipment deployment to solve the fading problem (Soldani and Dixit 2008). This advantage further enables a cost-effective enhancement of coverage, throughput and network capacity. The relay technique is very helpful in some harsh environments, for example, in rural areas where the population is sparsely distributed and traffic density is low that makes building traditional cellular access networks not economical. There has been a long history in the development of both theory and practice of wireless relays. The earliest concept of wireless relay can be traced back to year 1997 when Scott Guthery used it to construct the relay star network where the relay helps to connect fixed wireless nodes to central server (Guthery 1997). Many of the recent developments and their roots can be traced from Hua et al. (Hua et al. 2012, 2013). Another new angle of understanding the relay assisted communications is from the cooperative communication perspective (Nosratinia et al. 2004; Hong et al. 2007; Sheng et al. 2011). As shown in Fig. 1 where a source node S intends to transmit messages to the destination node D , the source node S sends the signal in the first time slot and the signal is received by both the destination node D and the relay node

R ; then in the second time slot, the relay node forwards the received signal to the destination node D . With an assistance of the relay node R , two copies of signal transmitted from the source S are received at the destination node D where one from S to D and another from S to R then to D . As the channels in those two links are generally independent, two copies of signals can be combined at the destination node D to achieve a more reliable detection. From the communication theory point of view, the performance gain comes from an inherent spatial diversity. As here the wireless relay helps to forward one-way message delivery, i.e., from source to destination, we refer to this channel model as one-way relay channel.

As illustrated in Fig. 1, although one-way relay channel can achieve a more reliable transmission, it requires one more time slot to complete message delivery compared to point-to-point transmission, which sacrifices spectrum efficiency. Later on, to compensate the spectral efficiency loss, in a scenario of two-way transmission where two nodes intend to exchange the messages with each other via a middle-placed relay node, the technique of physical-layer network coding (PLNC) is utilized to improve the spectrum efficiency (Wang and Tao 2012). The relay assisted two-way transmission is referred to as two-way relay channel. As shown in Fig. 2 where source node S_1 desires to transmit signal x_1 to source node S_2 and source node S_2 intends to transmit signal x_2 to source node S_1 , the whole transmission is completed in two time slots. In the first time slot, both source nodes transmit their signals to the relay node simultaneously. In this case, the relay node receives the combination

Fundamental Properties of Wireless Relays and Their Channel Estimation, Fig. 1

Wireless one-way relay channel.

Fundamental Properties of Wireless Relays and Their Channel Estimation, Fig. 2

Wireless two-way relay channel

of signals x_1 and x_2 . After performing certain processing, the combination is forwarded to nodes S_1 and S_2 in the second time slot. As two source nodes know their transmitted signals, the self-interference can be canceled from the received combination before decoding the desired signals. It is easy to observe that in two-way relay channel, two messages are delivered within two time slots. In contrast to the one-way relay channel, where two time slots are required to complete one message delivery, two-way relay channel significantly improves the spectrum efficiency.

Several relay processing strategies have been proposed in wireless relay channel. Basically, different strategies usually require different complexity and possess different performance. Two main strategies are amplify-and-forward (AF) strategy and decode-and-forward (DF) strategy. In AF strategy, the relay node simply amplifies the received signal and forwards it directly without decoding the messages. In DF strategy, the relay node decodes the messages from the received signals and regenerates new signals which are sent to the destination subsequently.

As the transmission protocol of the relay channel is quite different from the traditional point-to-point transmission, the corresponding physical layer techniques are greatly modified, especially the channel estimation which is used to obtain the channel state information required for physical layer designs including power allocation (Chen et al. 2017; Ma et al. 2014), precoding design (Cirik et al. 2014; Xu and Hua 2011; Yu and Hua 2010; Rong and Hua 2009; Rong et al. 2009), etc. In wireless relay channel, we generally need to estimate the channels of two-hop transmissions, i.e., from the source to the relay and from the relay to the destination. Lots of new and challenging problems are introduced. In this article, we aim to

provide a brief review of the channel estimation in wireless relay channel.

Foundations

According to transmission protocol, the two-hop channel estimation of wireless relay channel can be performed using the training signals received at the relay and the destination. If the relay node can perform the channel estimation and can transmit the training sequences, the two-hop channel estimation can be decoupled. For example, in the one-way relay channel, the first hop channel, i.e., the channel from the source S to the relay R , can be estimated at the relay node and the second hop channel, i.e., the channel from the relay R to the destination D , can be estimated at the destination node D separately. In this case, the overall channel estimation problem simply reduces to the two point-to-point channel estimations. In the two-way relay channel, we cannot directly decouple the two-hop channel estimation into two point-to-point channel estimation problems as it involves four independent channels. In this case, in the first hop, the channel can be considered as a multiple access channel (MAC) where received training signal at the relay node is used to estimate the channels from the source S_1 to the relay node R and from the source S_2 to the relay node R . While in the second hop, the channel can be treated as a broadcasting (BC) channel where the single training sequence sending from the relay node is received at the destination nodes and is then utilized to estimate the channels from the relay node R to two destination nodes S_1 and S_2 .

In another scenario, if the relay node cannot perform channel estimation or send training sequence, the channel estimation must be conducted at the destination nodes and corresponding channel estimation problem

becomes relatively more complicated. Under this setup, besides estimating the individual channels of two-hop transmission, estimating the combined channels, i.e., the cascade of two-hop channels, is an efficient way to simplify the channel estimation problems. The following brief review of the channel estimation in wireless relay channel is given from four classifications: single-antenna single-carrier case, single-antenna multi-carrier case, multi-antenna single-carrier case, and multi-antenna multi-carrier case.

Single-Antenna Single-Carrier Case

In Gao et al. (2008), the authors considered the channel estimation of single-antenna single-carrier one-way relay channel with multiple relay nodes. Assuming that h_i and g_i denotes the channel from source node S to the i -th relay node D_i and the channel from the i -th relay node D_i to the destination node D , respectively. Instead of estimating h_i and g_i individually, the authors considered to estimate the combined channel $h_i g_i$. The authors studied two estimation criterions, least square (L-S) and minimum mean-square-error (MMSE), by separately treating the unknown channels as deterministic variables and statistical random variables. The estimations of combined channel vector $\mathbf{w}$ for LS and MMSE using the received signal at the destination node $\mathbf{d}_2$ can be expressed as

$$\hat{\mathbf{w}} = \mathbf{A}_{\text{LS}} \mathbf{d}_2, \quad \hat{\mathbf{w}} = \mathbf{A}_{\text{MMSE}} \mathbf{d}_2 \quad (1)$$

where matrices $\mathbf{A}_{\text{LS}}$ and $\mathbf{A}_{\text{MMSE}}$ are related to the training signal and the beamforming matrix used at each relay node; furthermore, matrix $\mathbf{A}_{\text{MMSE}}$ is also related to the statistical information of the noise and channel. According to estimation theory, the authors derived the estimation error covariance matrix of two criterions. The training design was further investigated with an aim to minimize the estimation error, i.e., the trace of the estimation error covariance matrix. Different from the point-to-point channel estimation, the training design in this work included source training sequence design and relay beamforming matrices design. From the problem formulation,

it is found that the optimization of source training sequence design and relay beamforming matrices design can be combined together, which implies that only one matrix variable $\mathbf{C}$ needs to be equivalently optimized in the training design problem. For the LS estimation, the authors proved that the columns of $\mathbf{C}$ should be orthogonal with each other at the optimal solution, and optimal training design can be found. For the MMSE estimation, the authors transformed the training design problem into a convex semi-definite programming (SDP) problem and the optimal solution can be efficiently solved by modern interior point method based on existing convex optimization software.

Later on, the channel estimations of single-antenna single-carrier two-way relay channel were studied in Gao et al. (2009b) and Xie et al. (2014). In Gao et al. (2009b), the authors studied the two-way relay channel taking a time reciprocal property, which means that the channel from the source to the relay is equal to the channel from the relay to this source. With this assumption, the involved four unknown channels reduce to two unknown channels. Denote the channel from the source S_i to the relay node by h_i , similarly to the one-way relay channel estimation in Gao et al. (2008), the authors proposed to estimate the variables $|h_i|^2$ and $|h_1 h_2|$ at terminal S_i instead of estimating h_1 and h_2 . Two channel estimation criterions, i.e., the maximum-likelihood (ML) and linear maximum average effective signal-to-noise ratio (LMSNR), were utilized to obtain the estimations. In specific, the ML estimation treats the unknown channels as two deterministic values and channel estimation is obtained by solving the following problem (take source S_1 as an example)

$$\max_{|h_1|^2, |h_1 h_2|} \log p(z_1 | h_1, h_2) \quad (2)$$

where z_1 is the received signal at source S_1 and $p(z_1 | h_1, h_2)$ is the probability density function (PDF) of z_1 at given h_1 and h_2 . The LMSNR estimation treats the channels as unknown random values with known statistical information, and the channels are estimated by

maximizing the effective SNR. Moreover, the training sequences at two sources were designed aiming to minimize the Cramer-Rao lower bound (CRLB) and maximize the average effective SNR. The results of optimizations showed that the optimal training sequences at two sources should be orthogonal with each other. In Xie et al. (2014), the authors proposed to use the Bayesian approach to estimate the cascaded source-relay-destination channel. The maximum a posteriori (MAP)-based estimation schemes were developed to estimate the cascaded channel and the amplitude of individual source-relay channels with apriori knowledge of channel distribution information. Additionally, to deal with some practical constraints, an iterative least square-MAP algorithm was developed when noise variance was unknown.

Single-Antenna Multi-Carrier Case

The channel estimation of the single-antenna one-way relay channel was studied in Gao et al. (2011) and Wang et al. (2016) with the orthogonal frequency division multiplexing (OFDM) modulation. In this channel setup, the overall end-to-end channel from the source to the destination is the convolution of the channel $\mathbf{h}$ from the source node to the relay node and the channel $\mathbf{g}$ from the relay node to the destination node in the time domain. In Gao et al. (2011), to allow the destination node to estimate $\mathbf{h}$ and $\mathbf{g}$, besides sending the training signals at the source node, the relay superimposes its own training signal to the received training signal and sends them to the destination node. In this case, the transmit signal $\mathbf{r}_t$ at the relay can be represented as

$$\mathbf{r}_t = \alpha \mathbf{r}_r + \mathbf{t}_r \quad (3)$$

where $\mathbf{r}_r$ is the received signal at the relay node, α is the scaling factor used at the relay to satisfy the power constraint, and $\mathbf{t}_r$ is the new training signal superimposed at the relay node. It was shown that the closed-form expressions of estimated channel are generally not available in OFDM setup. To obtain an accurate estimation, an iterative channel

estimation was proposed where $\mathbf{h}$ and $\mathbf{g}$ were separately updated during the iteration. Different from Gao et al. (2011), the channel was estimated jointly with the unknown carrier frequency offset (CFO) and phase noise (PN) in Wang et al. (2016) under the OFDM framework. To enable the joint estimation of MIMO individual channel, CFO and PN at the destination, the training sequences are assumed to be transmitted at both the source and the relay. Let $\mathbf{y}^{[r]}$ denote the received signal at the destination when relay transmits the training signal and $\mathbf{y}^{[s]}$ denote the received signal at the destination when source transmits the training signal. According to the MAP criterion, the estimations of individual channel, CFO, and PN can be obtained by solving the following optimization problem

$$\left\{ \hat{\phi}^{[s-d]}, \hat{\eta}^{[s-d]}, \hat{\mathbf{h}}, \hat{\mathbf{g}} \right\} \propto \arg \min_{\phi^{[s-d]}, \eta^{[s-d]}, \mathbf{h}, \mathbf{g}} p \left(\phi^{[s-d]}, \eta^{[s-d]}, \mathbf{h}, \mathbf{g} | \mathbf{y}^{[s]}, \mathbf{y}^{[r]} \right) \quad (4)$$

where $\phi^{[s-d]}$ and $\eta^{[s-d]}$ denote the combined CFO from source to destination and the combined PN from source to destination; $\left\{ \hat{\phi}^{[s-d]}, \hat{\eta}^{[s-d]}, \hat{\mathbf{h}}, \hat{\mathbf{g}} \right\}$ denotes the estimated version of $\left\{ \phi^{[s-d]}, \eta^{[s-d]}, \mathbf{h}, \mathbf{g} \right\}$; $p \left(\phi^{[s-d]}, \eta^{[s-d]}, \mathbf{h}, \mathbf{g} | \mathbf{y}^{[s]}, \mathbf{y}^{[r]} \right)$ denotes the posterior distribution of the parameters of interests given $\mathbf{y}^{[s]}$ and $\mathbf{y}^{[r]}$. The ambiguities among the estimated PN, CFO, and channels were analyzed and showed that the estimated source-relay channel suffers from a phase ambiguity. Based on this analysis, a hybrid Cramer-Rao lower bound (HCRLB) for analyzing the performance was derived, which can effectively avoid the estimation ambiguities.

Regarding the single-antenna and multi-carrier two-way relay channel, the channel estimation was studied in the framework of OFDM modulation in Gao et al. (2009a). Different from Gao et al. (2011), the authors assumed that the training sequences were only transmitted from two sources while no training sequence was superposed at the relay node. Two estimation schemes, i.e., block-based and pilot-tone-based, were proposed to estimate the

cascaded source-relay-destination channel and the individual channels, respectively. The block-based estimation scheme uses all carriers in one or more OFDM blocks for channel estimation and generally applies to a scenario where the training sequence is long enough. The pilot-tone estimation scheme uses several pilots residing in one OFDM block to estimate the channel and applies to the scenario with a length-limited training sequence. The estimation ambiguities of two schemes were further analyzed. In specific, the authors showed that when the length of training sequence is larger than a threshold, only the sign ambiguity can be introduced and it does not affect the finally data decoding.

Multi-Antenna Single-Carrier Case

When considering multiple antennas at each node, the channel estimation of single-carrier one-way relay channel was investigated in Rong et al. (2012) and Kong and Hua (2011). The challenge of estimating the multi-input multi-output (MIMO) channels lies in the fact that the estimation variables become unknown matrices, while not the unknown values as in the single-antenna case. In Rong et al. (2012), the MIMO channels in source-relay-destination link and the MIMO channel in direct link were estimated without knowledge of the channel statistical information. In particular, the MIMO channel in direct link was estimated using LS criterion. Regarding the source-relay-destination link, according to the parallel factor (PARAFAC) analysis, the bilinear alternating least-squares (BALS) algorithm was proposed to obtain individual MIMO channels for source-relay link and relay-destination link. It was shown that with a mild length of training sequence, the MIMO channel matrices of two hops can be estimated up to permutation and scaling ambiguities. Moreover, the authors proposed to exploit the knowledge of the relay factors to remove the permutation ambiguity. In Kong and Hua (2011), the authors assumed that the statistical channel information was known in prior, and then the linear MMSE (LMMSE) estimation method was proposed to estimate the MIMO channels. To estimate the individual

MIMO channels in each hop of the source-relay-destination link, the authors proposed a two-step estimation strategy where in the first step, the MIMO relay-destination channel is estimated assuming that the relay node is able to transmit training sequences. With the estimated MIMO relay-destination channel, the MIMO source-relay channel is then estimated at the destination node utilizing the training sequence sent from the source. For the first step, the optimal structure of relay training sequence matrix was derived according to the statistical information of the relay-destination channel. While for the second step, an algorithm was developed to compute the optimal training sequence matrix used at the source and the optimal precoding matrix used at the relay.

Later on, the channel estimation of the MIMO single-carrier two-way relay channel was studied in Wang et al. (2015). Similar to Kong and Hua (2011), the authors assumed that the statistical channel information was known in prior under a Kronecker-correlation model. Additionally, the MIMO channels were estimated in a colored noise environment by considering the impact of the antenna correlation and the interference from neighboring users. To estimate each individual MIMO channel, the authors proposed to decompose the bidirectional transmission of two-way relay channel into two phases, i.e., MAC phase and the BC phase. The optimal LMMSE estimators were derived for each phase. Two iterative training design algorithms were further proposed to obtain the training sequences for the general conditions and they were verified to produce training sequences achieving near optimal channel estimation performance. For certain specific practical scenarios where the covariance matrices of the channel or disturbances are of particular structures, the optimal training sequence design guidelines were provided. To assess the estimation performance, the relationship between the estimation performance and the length of training sequences were established, which showed that when the training sequence length is shorter than the threshold, a lower bound of estimation performance exists no matter how to increase the powers.

Multi-Antenna Multi-Carrier Case

The MIMO channel estimation was extended to multi-carrier case for two-way relay channel in Kang et al. (2017). Instead of estimating the individual channels, the authors in this study proposed to estimate the convolution of two MIMO individual channels using the self-interfering link and information-bearing link under the LMMSE criterion. The training sequences were optimized with an aim to minimize the total MSE under the power constraints at the sources and the relay. To obtain the optimal training sequences, the authors derived optimal structure which then converted the training design optimization problem into a tractable convex form.

Key Applications

Wireless relay is one of the fundamental techniques in cellular wireless communications. It can be efficiently used to extend the wireless coverage and enhance the network throughput in harsh environments with low economy cost.

Future Wireless Network Architecture and Network Slicing

Hang Zhang, Nimal Gamini Senarath, Xu Li, Ngoc Dung Dao, and Hamid Farmanbar
Huawei Technologies Canada Co., Ltd., Ottawa, Canada

Definitions

Network slicing is an artificial intelligence (AI) technique to automatically develop and deploy multiple virtual networks (network slices) utiliz-

ing shared physical resources of wireless infrastructure networks.

Introduction

Many factors are driving the redefinition and redesign of future wireless network architecture. These factors include new types of customer services, the huge disparate service QoS requirements, new format of general wireless network infrastructure (GWNI) with the integrated clouds, new requirements of rapid deployment of networks, and new demands on openness of network development and operation. The development of advanced techniques, such as network function virtualization (VNF) (Original NFV White Paper 2012; NFV White Paper #2 2013; NFV White Paper #3 2014), SDN (ONF White Paper 2012; OpenFlow White Paper 2008; Open Flow-enabled SDN 2014), AI, and big data, has made virtualization of network possible in the future wireless network. A virtualized network (VN) or a network slice (NGMN 2016; NGMN 5G White Paper 2014) is a collection of network resources including virtualized network functions (NF), to serve certain types of services. Network slicing techniques are techniques which create multiple virtual networks using a common physical GWNI. Network slicing techniques are expected to revolutionize the future wireless network architecture and have profound impact on wireless telecommunication industry.

Considering the aforementioned facts, the future wireless network architecture design should enable:

- Support of a wide variety of service types with huge disparate service requirements
- Full automation of slice creation, adaptation, and maintenances
- Guaranteed slice performance during the lifetime of a slice
- Simplified and scalable network control and management
- Rapid GWNI adaptation to performance degradation and traffic load changes

- Openness to allow customers to define their slices and even operate their slices
- Openness to allow third-party involvement in certain types of network control and management
- Future-proof architecture

Given the requirements of future wireless network architecture, the fundamental design philosophy of future network architecture should be the modularization of network control/management functions and the service-customized composition of these modules. This philosophy leads to the following three key design principles:

Principle 1: Separation of Resource Assignment (Logical or Physical)-Related Functions from Other Functions

Resource assignment/allocation includes two levels:

- Slice level: define resource allocation/assignment to slices, and manage the multiplexing of the infrastructure network resource among multiple slices.
- End points (devices/servers of a slice) level: manage multiplexing of slice resources among multiple end points.

Other network control/management functions are not directly involved in the allocation/assignment of resources but provide the information required by the resource control/management functions.

Such a separation allows slice providers to retain exclusive control over resource allocation while allowing third parties to provide other functions. A slice provider provides network slices to slice customers and is a new and key role in future wireless network industry.

Principle 2: Object-Oriented Functions Classification

Network control/management functions need to be identified and classified based on the types of objects which are controlled and managed. Their objects include:

- End points of a slice (devices/servers): end point's location and activity state need to be monitored, and this information is needed for traffic packet delivery.
- Infrastructure equipment elements: the elements, including radio nodes, clouds (a DC can be abstracted as a network element with certain process capability), and transport network equipment, need to be configured. Their performance needs to be monitored, and this information is used for resource control and management.
- Operation data: data logged during network operation is raw data from which information, such as service performance, traffic load, and resource utilization, can be extracted. The operation data can be used for various purposes, e.g., infrastructure network performance optimization, slice performance assurance, etc.
- Composed/deployed slices: a deployed slice can be viewed as a network product whose performance and behavior need to be continuously monitored, and the status statistics are needed for slice performance assurance.
- Media content: media content can be created by content producers and shared by remote parties using wireless networks. Caching and sharing of media content within networks need to be managed to ensure efficient content cache and delivery.

Such a classification enables a systematic design and definition of clear scope and responsibility for each function class.

Principle 3: Reorientation of Network Control/Management Function Classes as Services

Reorientation of control/management function classes as services enables a service-based architecture (SBA). Such an architecture makes it easy to define interactions among these services and, furthermore, support openness of future wireless network development, operation, and management.

In this paper, the function classes which provide information for resource control/management services are referred to as network operation assistance services (NOAS).

Network Control and Management Services

Based on the design principles, the following network control/management services are identified and classified. These function classes are briefly described in paper “Future wireless network: MyNET and SONAC” (Zhang et al. 2015).

Resource Control and Management Services

There are two resource control and management services: service-oriented virtual network automatic creation (SONAC)-Com service for slice composition and SONAC-Op service for slice operation.

- Slice composition service – SONAC-Com service

SONAC-Com is an intelligent network slicing technique that utilizes advanced techniques such as AI in wireless networks. The key responsibility of SONAC-Com is to rapidly develop and deploy end-to-end service-customized slices based on customer service requirements using a common infrastructure resource pool. SONAC-Com is designed to enable full automation of slice life cycle control and management. SONAC-Com should have a hierarchical architecture, and its functions need to be tailored for different technical domains, such as RAN domains, transport network domains, and core network domains. The functions at different level of the hierarchy have different responsibilities. The SONAC-Com function at top level determines the requirements of domains in lower level (e.g., RAN domains, transport domains, and core network domains) based on end-to-end service requirement. The top-level SONAC-Com also coordinates resource

assignments proposed by domain SONAC-Com functions. Regarding resource allocation and configuration, slice definition includes three key aspects:

- Software Defined Topology (SDT) determines the needed network functions (NF) and the placement of NFs in the infrastructure network, e.g., clouds in core and in RAN. SDT also determines the end-to-end logical topology of a slice, i.e., logical links among these NFs and capacity requirement of each logical link.
- Software Defined Resource Assignment (SDRA) maps the logical topology to the infrastructure network. For example, SDRA in transport domain needs to map logical links between NFs in core domain and in RAN domains to transport networks.
- Software Defined Protocol (SDP) determines data transmission protocols. The end-to-end protocols (e.g., TCP or non-TCP) is determined by SDP at top level. SDP functions are tailored to different technical domains. For example, SDP in RAN domain determines the service-customized access link protocols, i.e., selected protocol elements and their placement in RAN network.

After the above design procedure, a slice can be deployed by configuring the infrastructure network equipment elements and instantiating and/or configuring NFs in clouds utilizing the techniques developed, e.g., by ETSI-NFV.

SONAC-Com is also responsible for on-demand slice adaptation based on changes in slice traffic load, performance of slice, and/or infrastructure resource pool size.

- Slice operation service – SONAC-Op service
- After the deployment of a slice, the traffic packets of authorized devices/servers of the slice are delivered over the slice. It is the responsibility of SONAC-Op to associate devices/servers with slices and to operate slices in order to provide end-to-end connectivity services. The provisioning of an end-to-end connectivity service by SONAC-Op, using the allocated slice resource, can

include three aspects: (1) determination of the packet delivery logical path from source device(s)/server(s) to destination device(s)/server(s), (2) determination of the mapping between the logical path and physical network, and (3) determination of protocol of the end-to-end connection, including end-to-end protocol and per link protocol, if on-demand and dynamic protocol determination is required. Similar to SONAC-Com, SONAC-Op includes functions distributed in domains in a hierarchical architecture. The functions of SONAC-Op are tailored to different technical domains. SONAC-Op function in core domain determines the logical path of packet delivery in core network. SONAC-Op functions in access link of RAN network nodes are responsible for real-time resource assignment to devices based on policies defined by SONAC-Com.

NOAS Services

NOAS functions are identified and classified below.

- Data log and Analytics Management – DAM service

DAM service controls and manages operation data. The key responsibility of DAM is on-demand data log and analytics. DAM is the only service that has the capability to log raw data and provide a unified log and analytics service to other NOAS services and authorized third parties.

- Infrastructure network Management – InfM service

InfM service controls and manages infrastructure network elements. The future infrastructure network resources should be “elastic” to adapt to the changes in traffic loads and performance of infrastructure networks. In order to enable network slicing, the available resources of infrastructure networks need to be abstracted and provided to SONAC-Com on an on-demand basis. The InfM functions are tailored to different technical domains. For example, InfM functions in RAN network are

responsible for on-demand powering on/off of radio network nodes. InfM needs service from DAM and provides its service to SOANC-Com and authorized third parties.

- Connectivity Management – CM service

CM service controls and manages reachability of devices. The key responsibility of CM service is to provide reachability information of devices for the purpose of traffic delivery over slices. The reachability includes two sets of information – where and when a device is available. The device location tracking/resolution function tracks device location and provides the information regarding where to deliver packets. The device activity configuration and tracking function configures and tracks the activity status of a device and provides information regarding when to deliver packets to a device. CM should be designed to fully utilize certain service-specific characteristics, such as the predictable patterns in downlink traffic packet transmission or location of devices. Thus CM functions can be customized to different services. CM should be designed to enable the decoupling of device name and its location, which allows device name to remain unchanged despite changing in its location. CM service has a hierarchical architecture that is essential to enable efficient routing. CM provides service to SONAC-Op and authorized third parties.

- Customer Service Management – CSM service

CSM service manages deployed slices. A customer slice can be viewed as a “product” of networks. After such a slice is deployed, (1) the rule of authorization of slice access needs to be maintained for controlling the use of the slice, (2) the performance of the slice needs to be assured during the entire life cycle of the slice, (3) a tight matching between traffic load and resources of the slice should be maintained, (4) usage of the slice by authorized devices/subscribers should be monitored for the purpose of charging, and (5) characteristics of traffic data of the slice and devices behaviors should be monitored for better operation of the slice. CSM service is

designed for aforementioned purposes. CSM service utilizes the DAM service to obtain the required information and provides its service to SONAC-Com for customer slice adaptation, to SONAC-Op for slice operation optimization, and to slice providers and authorized parties for charging purposes.

- Cache and Forwarding Management – CFM service

CFM service controls and manages media content. In the future, sharing media content using wireless networks will be one of the most popular types of services. A slice provider can define a dedicated media content cache and forwarding slice to enable the efficient sharing of media content. CFM service manages the media content registration, content cache, and cache access and forwarding. CFM service needs content-access-related information provided by DAM services for its operation. CFM provides information such as “destinations” of media content for caching purposes and “sources” of media content for content access purposes.

These NOAS services are deployed as slices since each NOAS service consists of functions distributed over infrastructure networks and interconnected.

Future Wireless Network Architecture

Given these identified network control/management services, one example of potential future wireless network architecture is shown in Fig. 1.

As shown in Fig. 1, SONAC-Com service is implemented as a slice. SONAC-Com is the most intelligent service in the overall architecture and is programmed by slice providers. SONAC-Com is capable of automatically and rapidly developing and deploying other slices. The resource pool that SONAC-Com uses to deploy slices is the generic wireless network infrastructure resource pool which includes all hard (e.g., clouds and telecommunication network equipment) and soft (e.g., spectrum) infrastructure resources. Based

on the requirements and descriptions of services, SONAC-Com defines slices and provides instruction on deployment of slices.

In this architecture, all the network control/management services and customer services are viewed and treated in the same way by SONAC-Com. This makes scalable and systematic network control and management possible. Such architecture naturally enables openness of network operation and management.

Development and Deployment of Slices

Development and Deployment of SONAC-Com Service Slice

SONAC-Com functions are developed and deployed by slice providers. After this procedure, other slices can be automatically developed by SONAC-Com as shown in Fig. 1. In order for SONAC-Com to develop other slices, SONAC-Com needs to maintain libraries of network functions (NF) designed for different technical domains and services. Each domain SONAC-Com function maintains the information describing its corresponding infrastructure networks. The information contains the specifications of physical network nodes, clouds, physical links, and topology. Given requests from slice customers, available infrastructure resources, and NF libraries, SONAC-Com service would be able to create all other slices.

Development and Deployment of SONAC-Op Service Slice

SONAC-Op slice is developed and deployed by the execution of the programmed SONAC-Com functions. This process includes (1) obtaining the SONAC-Op service requirement from slice providers; (2) deciding SONAC-Op function selection for different technical domains, the placement of SONAC-Op functions, the connections among these functions, and the policies that selected SONAC-Op functions need to follow during operation; and (3) deploying the SONAC-Op slice. After the deployment of SONAC-Op slice, the connections between SONAC-Com and

Future Wireless Network Architecture and Network Slicing, Fig. 1 Example of potential future wireless network architecture

SONAC-Op need to be established. A shared SONAC-Op slice can operate multiple customer slices. Customer-dedicated SONAC-Op slice can also be developed and deployed, if requested, at the same time a customer user plane (UP) slice is deployed.

Development and Deployment of NOAS Service Slices

The process of development and deployment of NOAS service slices is the same as that of a SONAC-Op service slice. After the deployment of NOAS slices, the required connections need to be established between NOAS slices and the SONAC-Op slice. The required connections also need to be established between NOAS slices. NOAS slices can be deployed before customer requests arrive. At the time customer slices are

deployed, these NOAS slices can be activated and/or configured. Customer-dedicated NOAS slices can also be developed and deployed, if requested, at the same time a customer user plane (UP) slice is deployed.

Development and Deployment of Customer Slices

A customer UP slice includes user plane (UP) NFs. The process of development and deployment of customer UP slices is the same as that of a SONAC-Op slice. Customers can define their private NF library and can even indicate the preferred placement of NFs. Some customer services may need UP plane slice, dedicated NOAS slices, and/or dedicated SONAC-Op slice. After a UP slice is deployed, connections need to be

established between the UP slice and SONAC-Op slice.

A customer slice can be deployed upon request. However, some purpose-specific UP slice can be deployed by slice providers prior to any customer request. A slice can be either dedicated to a single customer or shared among multiple customers if their service attributes and requirements are similar. For example, all of smart reading customers can share one UP slice – smart reading slice – and data traffic of these customers can be treated in the same way. Considering this scenario, when a service request is received, SONAC-Com needs (1) to determine which purpose-specific UP slice would be suitable for this customer, (2) to perform service admission control to make sure that the estimated resource requirement can be satisfied without causing any negative impact on other existing customers, and (3) to configure the corresponding SONAC-Op and NOAS functions.

Slice Resource Assignment Formats

There could be multiple formats of resource allocation to a slice.

- Format A (well-defined slice): an end-to-end slice with (1) definition of NFs and placement of the NFs in the infrastructure networks; (2) slice logical topology, i.e., logical links among NFs, including the links between NFs and RAN nodes; (3) capacities of logical links of this slice; (4) mapping of logical links to infrastructure networks; and (5) definition of end-to-end protocols and per logical link protocols.
- Format B (moderately defined slice): similar to Format A. However, there is no (3) definition of capacities of logical links of the slice.
- Format C (loosely defined slice): slice with only (1) definition of NFs and placement of NFs in the infrastructure network.

Variations of these formats are also possible. The format should be selected based on service attributes, e.g., the degree of statistical predictability of traffic load pattern, the degree of device mobility, and the service quality

requirement. The network load and congestion control is another factor which impacts on the selection of format. Since Format A defines logical link capacities, the network-level traffic congestion control can be managed at the slice level by SONAC-Com, which “sees a bigger picture” of load distribution over infrastructure networks. Furthermore, complexity balance between SONAC-Com and SONAC-Op may also need to be considered. To define a well-defined slice requires a higher level of intelligence from SONAC-Com. However, a Format A slice enables the relative simple process of SONAC-Op, which results in shorter process latency and less signaling overhead. Format C requires more intelligent SONAC-Op process but less complicated SONAC-Com process.

Operation of a Deployed Slice

After a slice is deployed, the slice is ready to deliver packet traffic. Different functions of SONAC-Op can be designed for different slice formats.

Format A: After a well-defined end-to-end customer UP slice is deployed, SONAC-Com needs to provide slice information to SONAC-Op. A Format A slice enables a slice-level forwarding rule, i.e., slice-level routing table, to be pre-configured. Therefore the procedure of per end point (device/server) end-to-end path establishment can be simplified. Per device uplink traffic packet delivery becomes the selection of the right “entry point” of such a slice by RAN access nodes. The downlink data packet delivery to a mobile device becomes the selection of the right “exit point” of such a slice by network. The NFs in UP can perform a virtual router function. The responsibility of SONAC-Op for the purpose of packet delivery is to control and to manage the end point forwarding tables at virtual routers utilizing CM services. Such a packet delivery approach can be viewed as a packet-oriented scheme over virtual networks. Format A slice definition together with virtual router-based packet delivery approach combines the circuit-oriented technique at slice level and the packet-oriented technique at packet level. Furthermore,

a Format A slice designed for customers, such as vertical industry customers who collect data from their devices or control the behaviors of all these devices, can significantly simplify the operation of slice. In this case, SONAC-Op may not need to perform path management at per device level since such a type of service does not need to differentiate between devices. For operation of Format A slices, SONAC-Op needs to control resources allocation among slices based on the capacity requirements of logical links of slices in order to ensure slice-level QoS.

Format B: The responsibility of SONAC-Op in Format B slices is similar to the responsibility in Format A slices. However, since there is no definition of capacities of logical links, slice-level performance assurance may be more challenging. For example, if a radio node supports two slices, SONAC-Op at access link of the radio node – acting as access link scheduler – may under-provision or over-provision resources to these slices.

Format C: The responsibility of SONAC-Op in Format C slices may need to perform on-demand configuration of interconnection of NFs based on the dynamic service requirement, in addition to those of Format B. SONAC-Op also needs to control the per device end-to-end path establishment.

The interaction between SONAC-Op and other slices are illustrated in Fig. 2.

As shown in Fig. 2, CM NOAS service provides device reachability information to SONAC-Op for packet delivery path control and management. CSM NOAS service provides behavior context information of devices of a slice

to SONAC-Op for slice operation optimization. SONAC-Op performs slice operation based on the real-time information provided by NOAS services and pre-configured policies.

Adaptation of Deployed Slices

SONAC-Com is programmed to automatically and rapidly modify existing slices. There is a number of factors that may trigger slice adaptation.

- Customer service assurance aspect

Slice performance is monitored by functions of CSM service with assistance of DAM service after a slice is deployed. If CSM identifies abnormal events, such as a mismatching between resources and traffic load of a slice, CSM service will trigger a slice adaptation.

- Infrastructure resource optimization aspect

Performance assurance of infrastructure networks and optimization of infrastructure resource utilization can result in changes in infrastructure network topology and capacity. This can cause the adaptation of existing slices. InfM can identify these changes with assistance of DAM service and trigger a slice adaptation.

- Device service aspect

For some extreme cases where a customer slice is dedicated to one customer with a group of co-located mobile devices, e.g., an emergency ambulance customer, some service-specific NFs need to be deployed close to the edge of the network and need to migrate along with the mobile devices. In this case, the slice topology may be adapted to the movement of the mobile devices.

- Customer service aspect

For some services that utilize deployed sensors to monitor changes in, e.g., temperature, in order to detect occurrence of certain incidences, a dedicated slice can be deployed for such a service. The occurrence of certain incidences may lead to spikes in traffic. This requires SONAC-Com to rapidly modify the slice resources to adapt to the change in traffic load. Such incidences can be detected

Future Wireless Network Architecture and Network Slicing, Fig. 2 Slice operation

Future Wireless Network Architecture and Network Slicing, Fig. 3 Adaptation of slices

by, e.g., service application functions. In this case, application functions may trigger a slice adaptation.

Slice adaptation and interaction among SONAC-Com and other NOAS slices are illustrated in Fig. 3.

As shown in Fig. 3, NOAS services, such as CSM and InfM services, obtain information of performance of slices and infrastructure networks by utilizing the service of DAM. CSM and InfM services provide status reports to SONAC-Com when certain pre-configured conditions are met. SONAC-Com makes decision on slice adaptation based on the information and policies pre-configured by slice providers.

Openness and New Business Model Support

In future wireless network industry, a new business model can be expected where multiple types of players will be involved in supporting communication services. These players could be:

- Slice providers who provide end-to-end slices by using the integrated generic infrastructure resource provided by infrastructure providers
- Slice customers (owners) who request and obtain end-to-end slices from slice providers and may control/manage the slices to provide further services to their customers (consumers), e.g., subscribers
- Slice customers (consumers) who consume slice resource to obtain communication service, e.g., mobile subscribers

The design philosophy discussed in this paper enables flexible distribution of network control/management services/functions among players, i.e., these control/management services in the discussed architecture can be provided by slice providers or by other players such as authorized third parties. This architecture also makes it possible to share various status information with authorized third parties. For example, DAM service can provide on-demand information exposure services to authorized third parties. Utilizing DAM service, CSM service can provide slice status information to customers of slices, and InfM service can provide information of infrastructure network resource and traffic load to authorized third parties.

This new business model needs new business revenue support. In the discussed architecture, NOAS services, such as CSM and DAM services, can provide sufficiently detailed and granulated information such that charging information can be derived.

Conclusion

Network virtualization and automation are expected to have profound impact on the wireless network industry. In the future, advanced techniques, such as AI and big data, will become essential techniques for network virtualization and slicing. With the development of these technologies and with a better understanding of future service demands, the future wireless networks will be designed to provide true ubiquitous connectivity services to all types of customers and will benefit all walks of life and whole society.

Definitions

Zero-rating Internet is the concept of allowing end-users to access the basic services of some websites via mobile network operators (MNOs) without charge. More specifically, the MNO does

not subtract data usage of zero-rated services from the end-users' data quota.

Sponsored content (i.e., sponsored data) is a similar context to zero-rating, where the end-users still get access to some websites and contents for free or with a discount. However, unlike zero-rating, in sponsored content the websites pay the cost of the sponsored contents' bandwidth to the MNOs.

A *zero-rating platform* is a relaying service which allows websites to easily make their content available as zero-rating through the platform.

Historical Background

Websites such as Facebook, Google, and Wikipedia have been providing zero-rating access of their services (e.g., Facebook Zero, Google Free Zone, Wikipedia Zero) with partnership of some mobile network operators (MNOs) in several less developed countries. Their primary aim is to provide free basic access of their services for people in less developed countries and show them the true value of Internet services (de Miera Berglind 2016). Most of the works related to zero-rating are focused on regulations as in de Miera Berglind (2016) and Sambuli (2016) and the assessment of its benefits and costs as in Futter and Gillwald (2015) and Eisenach (2015).

In addition to zero-rating services of particular websites, zero-rating platforms are provided

by some content and service providers. An example of a zero-rating platform, launched in August 2013, is *Free Basics* (formerly called Internet.org) that is provided by Facebook to bring affordable access of selected Internet services to the people of less developed countries. When an MNO becomes a partner with this platform, the MNO allows its customers to receive basic free access to websites that are included in the platform. As a response to the concerns over net neutrality, in May 2015, Facebook announced the platform as an open program for developers to create services that integrate with the platform. Consequently, *Free Basics* allows websites to provide their basic services through the platform for free on condition that they meet the basic technical requirements of the platform to make a simplified version of their website that is data-efficient (e.g., services that use VoIP, video, file transfer, or large photos are not compatible). Neither the platform nor the participating websites pay the MNOs for the data that the end-users consume through *Free Basics* (Int 2017).

Technically speaking, *Free Basics* works similar to a virtual private network (VPN) or a proxy service. Partner MNOs do not charge their end-users' traffic to/from *Free Basics* servers. End-users of the partner MNOs can connect to *Free Basics* servers, and afterward their requested websites are relayed by the service. Once connected to *Free Basics*, the end-user is only allowed to see a simplified version of the participating websites at the platform. An application and a landing page are provided by *Free Basics* that show a list of available websites to the end-users.

Currently, different bundle pricing schemes are commonly employed by many MNOs. In these schemes, usually a limited amount of voice calls and data during an interval are sold to the end-users as a prepaid bundle. Moreover, usage-based pricing is imposed for unbundled and overage calls and data (Sen et al. 2013). A bundle pricing scheme for the MNO with inclusion of zero-rating services in the bundles is proposed in Asghari et al. (2017), and the circumstance is

modeled as a Stackelberg game with an MNO and its end-users as the players of the game where the MNO decides about provisioning of zero-rating service in its bundles as well as the bundles prices and the end-users respond by deciding about buying the bundles. The proposed model assists the MNO to make a decision on including zero-rating services in its bundles as well as appropriate pricing scheme. Numerical studies show that depending on the end-users' preferences, the MNO may increase its profit by including zero-rating services in its bundles (Asghari et al. 2017).

Recently, the context of sponsored content has attracted lots of attention for its economic challenges. Unlike the zero-rating concept that the only profit source of the MNO is from the end-users, in the sponsored content concept, the MNO gets payments from the content providers in addition to the end-users, while the content providers pay a fraction or complete cost of the sponsored contents' bandwidth to the MNO instead of the viewers to attract more viewers. The work of Andrews et al. in (2013) can be considered as a fundamental work on economic aspects of sponsored content. They considered a Stackelberg game with an MNO and a content provider, where the MNO sets a pricing schedule to the content provider for sponsoring and the content provider responds by deciding how much content to sponsor. They concluded that a coordinating contract can be designed aiming at maximizing total system profit. A methodology in Andrews et al. (2014) is developed for extracting required parameters of the model in Andrews et al. (2013). Later in Jin et al. (2015), Jin et al. extended the model of Andrews et al. (2013) even further by including multiple content providers and considering different versions of the model. Additionally, Zhang and Wang studied the impact of sponsored data strategy on content providers with different scales (Zhang and Wang 2014). Finally, Joe-Wong et al. considered content providers' choices and introduced a framework for content providers to decide which and how much content to sponsor (Joe-Wong et al. 2015).

Foundations

A zero-rating platform such as *Free Basics* is unable to provide any services to the end-users unless the end-users can access it through the MNOs for free. However, the MNOs only grant a free access to zero-rating platforms if the MNOs believe that it will be beneficial for them. Considering that in current setup of zero-rating platforms no monetary reward is transferred from the participating websites and zero-rating platform providers to the partner MNOs, the MNOs seek for the extra profit in this partnership from end-users side. Thus, the MNOs face a question of whether to cooperate with zero-rating platforms or not.

The interaction between an MNO and its end-users toward providing their access to zero-rating platforms' services can be modeled by a variant of Stackelberg game where a bundle pricing scheme of the MNO is considered. Thereby, the effects of including zero-rating platforms' services in the bundles can be studied (Asghari et al. 2017). The results of the game assists the MNO to react to this new trend and make a decision on provisioning of zero-rating services in its bundles as well as determination of appropriate pricing strategies.

Figure 1 shows the system model and its major players. A MNO and its end-users are considered as the active players of a game where each end-user may prefer regular services, zero-rating services, or both. All websites are available for the end-users through regular rated links provided by the MNO. Meanwhile, some partially opened or closed zero-rating platforms are presented, and they essentially use zero-rated links brought by the MNO to communicate with its end-users. In this context, websites can use zero-rating platforms as relays to present their services as zero-rated to the end-users.

Considering an MNO in a region, it faces with a question of whether it should cooperate with zero-rating platforms and offer zero-rating services to its customers or not. In case of offering zero-rating services, the MNO may change the prices to compensate the cost of zero-rated traffic and substitution effects of zero-rating services on non-free data usage.

To model the circumstance as a game, it is assumed that the MNO offers a bundle with limited amount of voice calls and data during an interval. The bundle may include zero-rating platforms' services or not, and the MNO only provides the bundle either with or without zero-rating services for all of the customers. The

Game Theoretic Modeling of Zero-Rating Internet Provisioning, Fig. 1 Zero-rating system model

Game Theoretic Modeling of Zero-Rating Internet Provisioning,

Fig. 2 Extensive form representation of the game (players: MNO and customers)

bundle without zero-rating services is called “regular bundle,” and the bundle with zero-rating services is called “zero-rating bundle” where the zero-rating bundle includes every services of the regular bundle, but its price may be different. A simple example of a regular bundle can be considered as prepaid minutes of call package including data quota or without data.

The situation can be modeled as a variant of Stackelberg game which is a sequential game, where the MNO is the leader and moves first and the customers are the followers. It is assumed that the zero-rating platforms are formed and they are willing to cooperate with the MNO. Figure 2 shows the extensive form representation of the game which consists of two stages. At the first stage, the MNO chooses to offer a bundle with zero-rating platforms’ services included or with the regular services alone, along the prices of the bundles (p_Z and p_R). At the second stage, the customers observe the MNO’s decision and choose whether they want to buy the offered bundle or not which forms the total demand of the customers (v_Z and v_R). The game is solved with backward induction where the followers decide how many bundles they buy considering the decisions of the leader. The leader can anticipate the follower’s best response and choose the prices and include zero-rating platforms’ services to maximize its profit. The solution of the game is a subgame perfect Nash equilibrium (SPNE) and contains the best strategies of the players, where

no player can benefit by only changing its own strategy.

It is considered that there is v_0 potential customer in the region. Net utility function of customer i for buying a bundle is considered as follows:

$$U_i = \begin{cases} \phi_i L_Z + \theta_i L_R - p_Z & \text{Buys a zero-rating bundle} \\ \theta_i L_R - p_R & \text{Buys a regular bundle} \\ 0 & \text{Buys no bundle} \end{cases} \quad (1)$$

where ϕ_i and θ_i are customers’ preference parameters regarding the zero-rating services and a regular bundle, respectively. Both ϕ_i and θ_i are considered independent and uniformly distributed in $[0,1]$. In addition, $L_Z \geq 0$ and $L_R \geq 0$ are the highest satisfaction levels (i.e., valuation) that a customer may get by having zero-rating services and a regular bundle, respectively. Moreover, p_R is the price for a regular bundle, and p_Z is the price for a zero-rating bundle which includes the regular bundle services as well. Every customer i selects one of the three options in its utility function to maximize its utility based on its ϕ_i and θ_i , the offered prices p_R and p_Z , and the type of offered bundle (zero-rating or regular).

Figure 3 shows two preference parameters ϕ and θ and the way that customers decide on any of their three choices given their utility function defined in (1). Figure 3a shows the preference

Game Theoretic Modeling of Zero-Rating Internet Provisioning, Fig. 3 Customers sensitivity map for (a) regular bundle, (b) zero-rating bundle when $((p_Z < L_R) \& (p_Z < p_R))$, (c) zero-rating bundle when $((p_Z < L_R) \& (p_Z < p_R))$, and (d) zero-rating bundle when $(p_Z \geq L_R)$. (Source: Asghari et al. 2017)

map of the customers when the regular bundle is the only offered bundle. It is obvious that $\frac{p_R}{L_R} \leq 1$. Figure 3b–d show the preference map of the customers when the zero-rating bundle is the only offered bundle, while Fig. 3b, c show the map when $(p_Z < L_R)$, and Fig. 3d shows the map when $(p_Z \geq L_R)$. Figure 3c shows a special case of Fig. 3b where $(p_Z < p_R)$. For simplicity, it is only considered the case of $p_Z \leq L_Z$.

The maps in Fig. 3b–d are divided into different regions that are marked with (I) to (V). The division lines show indifference points regarding the consumer preferences on the line. The total

demand functions of the customers for different type of bundles are derived as follows.

When the MNO only offers the regular bundle, Fig. 3a is applicable, and the customers only choose between buying a regular bundle or not buying at all. A customer who has $\theta = \frac{p_R}{L_R}$ is indifferent between buying or not. Thus, v_0 multiplied by the segment from $\theta = \frac{p_R}{L_R}$ to 1 determines the total demand function of the customers who buy the regular bundle which is equal to:

$$v_R = v_0 \left(1 - \frac{p_R}{L_R} \right). \quad (2)$$

When the MNO only offers the zero-rating bundle, all customers in regions (I), (II), and (III) will buy it. The line that separates these regions with regions (IV) and (V) corresponds to the condition of $\phi = \frac{p_Z}{L_Z} - \theta \frac{L_R}{L_Z}$, and the total area of all regions is equal to one. Thus, v_0 multiplied by the combined area of regions (I), (II), and (III) determines the total demand function of the customers who buy the zero-rating bundle which is equal to:

$$v_Z = \begin{cases} v_0 \left(1 - \frac{p_Z^2}{2L_Z L_R}\right) & \text{Otherwise} \\ v_0 \left(1 - \frac{2p_Z - L_R}{2L_Z}\right) & \text{if}(p_Z \geq L_R). \end{cases} \quad (3)$$

Finally, there are customers that always buy the bundle either with or without zero-rating services (i.e., $Z \cap R$) which are placed at regions (II) and (III). Their demand can be shown as:

$$v_{(Z \cap R)} = \begin{cases} v_0 \left(1 - \frac{p_Z^2 - 2p_Z p_R + p_R^2 + 2p_R L_Z}{2L_Z L_R}\right) & \text{Otherwise} \\ v_0 \left(1 - \frac{p_R}{L_R}\right) & \text{if}((p_Z < L_R) \& (p_Z < p_R)) \\ v_0 \left(1 - \frac{2p_Z L_R - L_R^2 - 2p_Z p_R + p_R^2 + 2p_R L_Z}{2L_Z L_R}\right) & \text{if}(p_Z \geq L_R). \end{cases} \quad (4)$$

These demands are the best responses of the customers to the leader's decision. The MNO is aware of these demands, and it decides on the prices and the choice of offering zero-rating services or not in the bundle to maximize its profit. Considering these demands, profit of the MNO when it includes zero-rating services (shown with π_Z) and when it does not include zero-rating services (shown with π_R) can be written as:

$$\pi_Z = (p_Z - c_R - c_Z)v_Z - c_S v_{(Z \cap R)}, \quad (5)$$

$$\pi_R = (p_R - c_R)v_R, \quad (6)$$

where c_R is the average cost of the regular services at the bundle for the MNO and c_Z is the average cost of including zero-rating services at the bundle for the MNO. Moreover, c_S is the substitution cost of zero-rating services at the bundle to the profit of the MNO. In other words, c_S is imposed by those customers who always buy the bundle either with or without zero-rating services ($Z \cap R$). When the regular bundle is the only offered bundle, the customers in ($Z \cap R$) would buy the regular bundle. Further, when zero-rating bundle is the only offered bundle, they will still buy the bundle. However, in this case, they may consume less non-free data than regular bundle

due to availability and substitution effect of zero-rating services in the zero-rating bundle.

To suggest the MNO to offer zero-rating platforms' services with the bundle or not and choose the best price for the bundle, the games is solved as follows:

First, the optimal p_R that maximizes π_R is found. Because of $\frac{\partial^2 \pi_R}{\partial p_R^2} < 0$, the solution of $\frac{\partial \pi_R}{\partial p_R} = 0$ gives the optimal p_R as:

$$p_R^* = \frac{L_R + c_R}{2}. \quad (7)$$

Furthermore, the optimal π_R becomes:

$$\pi_R^* = v_0 \frac{(L_R - c_R)^2}{4L_R}. \quad (8)$$

To find optimal p_Z and π_Z , the solution of $\frac{\partial \pi_Z}{\partial p_Z} = 0$ is found as:

$$p_Z = \begin{cases} \frac{A_1 \pm \sqrt{A_2}}{3} & \text{if}((p_Z < L_R) \& (p_Z \geq p_R)) \\ \frac{A_3 \pm \sqrt{A_4}}{3} & \text{if}((p_Z < L_R) \& (p_Z < p_R)) \\ A_5 & \text{if}(p_Z \geq L_R) \end{cases} \quad (9)$$

where

$$\begin{aligned} A_1 &= c_R + c_Z + c_S, \\ A_2 &= (A_1)^2 + 6L_Z L_R - 3c_S L_R - 3c_R c_S, \\ A_3 &= c_R + c_Z, \\ A_4 &= (A_3)^2 + 6L_Z L_R, \\ A_5 &= \frac{L_R + 2L_Z + c_S + 2c_R + 2c_Z}{4} - \frac{c_S c_R}{4L_R}. \end{aligned}$$

Only those situations that $A_2 \geq 0$ are considered. For $(p_Z \geq L_R)$, we have $\frac{\partial^2 \pi_Z}{\partial p_Z^2} < 0$; thus the solution of $\frac{\partial \pi_Z}{\partial p_Z} = 0$ gives the optimal p_Z in (9). However, for $((p_Z < L_R) \& (p_Z \geq p_R))$, we have $\frac{\partial^2 \pi_Z}{\partial p_Z^2} < 0$ only at $p_Z > \frac{A_1}{3}$, which is the part that it is maximized. Likewise, $p_Z > \frac{A_3}{3}$ should be selected for $((p_Z < L_R) \& (p_Z < p_R))$ case. Therefore, we take both plus signs of $\pm$ in (9). In addition, p_Z can be eliminated from the conditions in (9) which transforms it into:

$$p_Z^* = \operatorname{argmax}_{p_Z \in \Psi} (\pi_Z), \quad (10)$$

where

$$\begin{aligned} \Psi = \left\{ \min \left(\max \left(\frac{A_1 + \sqrt{A_2}}{3}, p_R^* \right), L_Z, L_R \right), \right. \\ \min \left(\frac{A_3 + \sqrt{A_4}}{3}, p_R^*, L_Z, L_R \right), \\ \left. \max (\min (A_5, L_Z), L_R) \right\}. \end{aligned}$$

Note that the expression in (10) is basically a selection algorithm which chooses p_Z^* among six discrete points. By substitution of p_Z^* from (10) into (5), the optimal π_Z^* can be obtained.

In order to determine the MNO's optimal decision, *profit margin* of the MNO is defined as $\Delta = \frac{\pi_Z^* - \pi_R^*}{\pi_R^*}$ which indicates the ratio of changes in MNO's profit when it includes zero-rating services in the bundle to the profit when it does not include the zero-rating services in the bundle. The MNO includes zero-rating services in the bundle only if $\Delta \geq 0$. Finally, the determined p_Z^* , p_R^* and the decision to include zero-rating

services when $(\Delta \geq 0)$ are in the unique SPNE of the game.

Figure 4 shows numerical examples. In the examples, we set $c_R = 1$, $c_Z = 0$, and $c_S = 0$ unless otherwise stated. Figure 4a shows $\Delta > 1$ (i.e., the MNO includes zero-rating services) with respect to the ratio of L_Z to L_R . Figure 4b is similar to Fig. 4a focusing on how L_R changes. It can be observed that as $\frac{L_Z}{L_R}$ increases, the profit margin of the MNO increases as well by offering zero-rating bundles. That is due to higher valuation of the end-users for zero-rating services. This effect weakens as L_R increases. Since, for small L_R , the MNO has low profit from regular bundles, and offering zero-rating bundles would have a greater impact on its profit. An important observation is that in most cases for $\frac{L_Z}{L_R} < 0.5$, the MNO is better off without zero-rating bundles. Therefore, the MNO tends to increase L_Z of the end-users by participating with zero-rating platforms that are more attractive for them.

Figure 4c, d show the impact of c_S and c_Z to the profit margin when all the other parameters remain the same. The increase in both of these costs reduces Δ which is evident, and c_Z is more effective than c_S because c_Z applies to all customers' demand. However, c_S only applies on demand of customers in $Z \cap R$ which are a portion of all customers. c_S can be interpreted as loss in out-of-bundle data sales caused by substitution effects of zero-rating services in the bundle.

In conclusion, the numerical examples show that depending on the costs and end-users preferences, the MNO can increase its profit by including zero-rating services in the bundle and choosing the bundle price in (10) for the cases of $\Delta > 1$.

Key Applications

As mentioned before, in zero-rating Internet solutions such as *Free Basics*, no monetary reward is transferred from participating websites and zero-rating platform providers to the MNOs. That is one of the major obstacles in provisioning of

Game Theoretic Modeling of Zero-Rating Internet Provisioning, Fig. 4 Numerical examples showing (a–b) positive Δ with optimal p_Z^* when $c_R = 1$, $c_Z = 0$, $c_S =$

0; (c) positive Δ with optimal p_Z^* when $c_R = 1$, $c_Z = 0$; and (d) positive Δ with optimal p_Z^* when $c_R = 1$, $c_S = 0$. (Source: Asghari et al. 2017)

zero-rating Internet that discourages the MNOs to participate in zero-rating practices. However, considering the provisioning of zero-rating Internet as a new opportunity for the MNOs to boost the sales of their services in the form of bundles by attracting more customers can make the provisioning of zero-rating services profitable for the MNOs and facilitate its provisioning. In addition, when multiple MNOs are considered, provisioning of zero-rating services can play an important role in their competition.

Definition

Vehicle-to-grid (V2G) regulation services are services in which plug-in electric vehicles, such as battery electric vehicles (BEVs), plug-in hybrid electric vehicles (PHEVs), or hydrogen fuel cell electric vehicles (FCEVs), communicate with the power grid so as to provide frequency regulation services to the grid by manipulating their charging or discharging rates.

Past: Historical Background

Electric Vehicle and Vehicle-to-Grid Regulation Services

Due to the worldwide concerns on global warming, many countries have established green policies to restrain the greenhouse gas emissions, such as promoting electric vehicles (EVs). Based on the report of EV sales in 2018 (Bloomberg New Energy Finance 2018), the sales of EVs will increase from 1.1 million cars worldwide in 2017 to 11 million cars in 2025 and then toward 30 million cars in 2030 (as shown in Fig. 1) as EVs become cheaper than internal combustion engine (ICE) vehicles. The increasing penetration of EVs in transportation will not only bring environmental and economic benefits, but also help improve the reliability and stability of the power grid. Specifically, grid-connected EVs can discharge or charge their batteries to inject power to or absorb power from the grid so as to provide ancillary services to the grid. This concept is defined as the vehicle-to-grid (V2G) technique. As shown in Fig. 2, EVs charge (discharge) power from (to) the grid through a V2G unit, which includes a bidirectional inverter to enable bidirectional power exchange between EVs and the grid. With the help of smart control units, V2G unit, together with its subordinate EVs, can exchange power with the grid in response to the control signals of the grid. This enables EVs to provide ancillary services to the grid.

Among the ancillary services of the power grid, frequency regulation services are important and the most expensive ancillary services.

Vehicle-to-Grid
Regulation: Past,
Present, and Future,
Fig. 1 EV market trend

Game Theory Meeting Vehicle-to-Grid Regulation: Past, Present, and Future, Fig. 2 Vehicle-to-grid diagram

Frequency regulation services aim to maintain the grid frequency at its nominal value through active power compensation, so as to keep real-time power balance in the power grid. Frequency regulation services include regulation-up, which injects power from generation assets to the grid, and regulation-down, which absorbs power from the grid to loads. Some recent studies show that the bidirectional EV chargers (Kwon and Choi 2017) and power electronics inside EVs (Merrill et al. 2015) can compensate well for frequency regulation-down and regulation-up signals through battery charging/discharging control. Therefore, an aggregation of EVs, which constitutes a distributed energy storage system as a V2G system, can bring large capacities

for providing frequency regulation services. The concept of V2G regulation services is defined to refer to the regulation services provided by a V2G system. It is able to smooth out the power fluctuations of the power grid and thus is important for supporting the integration of renewables (Kempton and Tomi 2005).

Game Theory Meets Vehicle-to-Grid Regulation Services

To provide V2G regulation services, several existing studies have considered the coordination of charging/discharging behaviors of EVs from the perspective of grid optimization. Based on the control techniques, the existing work can be divided into (1) the grid measurement

approach (Pham et al. 2016; Yang et al. 2013) and (2) the optimization-based approach (Lin et al. 2014; Shao et al. 2016; Chen et al. 2017). The former measures the grid frequency and then uses droop characteristics to compensate for the frequency deviation. It allows EVs to respond quickly to frequency regulation signals with very limited communication between EVs and the power grid (Pham et al. 2016; Yang et al. 2013). However, since this approach only relies on the frequency regulation signals which lacks sophisticated coordination scheme of EVs, suboptimal solutions are generally yielded for V2G regulation services. For the optimization-based approach, a global optimization problem is formulated to guide the charging/discharging schedules of EVs toward the global optimum. Lin et al. (2014) proposed optimal V2G control strategies for EV aggregators based on both offline scheduling and online scheduling. Decentralized algorithms were also designed to solve the optimal V2G control problem based on the gradient projection method. To coordinate a large scale of EVs, hierarchical architectures of the V2G system are well studied in recent years (Shao et al. 2016; Chen et al. 2017). A two-level charging scheduling framework was proposed for a large population of EVs (Shao et al. 2016). In this framework, the charging schedules of EVs are coordinated by local EV aggregators, and these EV aggregators are further controlled by the grid operator. The Benders decomposition approach was applied so as to solve the hierarchical charging scheduling problem. Chen et al. (2017) proposed a general framework for hierarchical V2G system, which has no restriction on the number of levels of the system. Smart V2G aggregators are employed at different levels to facilitate the grid operator coordinating the charging/discharging behaviors of EVs. Through this approach, the computational burden of the grid operator can be tremendously reduced, and the scalability of the V2G system can be enhanced.

The aforementioned approaches are from the perspective of grid optimization and assume that EVs follow the instructions of the grid operator or aggregators. Nevertheless in the real-world

operations, EVs are selfish individuals which are owned by different EV owners. These owners may be more concerned about the utilities of their EVs and the degradation issue of the EV batteries, instead of grid operations. Therefore, EVs may fail to reach an agreement with the grid because of their conflict of interests. It is thus a pressing issue on how to motivate EVs to participate into the V2G system. Game theory can provide a solution to this issue. Game theory studies how intelligent rational decision-makers act while considering the conflict and cooperation among them. Instead of following the instructions from a centralized controller, in game theory, each decision-maker makes its own actions that can maximize its utility. Applying game-theoretic approaches to V2G regulation can ensure the fulfillment of the utility of individual EV since EV can choose its optimal charging/discharging strategy to maximize its utility. Therefore, game-theoretic approaches can motivate the participation of EVs in V2G regulation. Based on the nature of the game, game-theoretic approaches can be classified as non-cooperative approach and cooperative game approach. In non-cooperative game, players are competitive and only take their own utilities as the decision goals. In contrast, in cooperative game, players collaborate with each other to some extent so as to increase their social welfare or achieve certain social goals. Some existing studies (Wu et al. 2012; Tan and Wang 2017) have already consider applying game-theoretic approaches to V2G regulation, say, using cooperative game approach (Wu et al. 2012) and non-cooperative game approach (Tan and Wang 2017). Wu et al. (2012) proposed a cooperative game-theoretic model to investigate the interaction between an aggregator and EVs in a V2G market. A backup battery bank (BBB) is also deployed in the aggregator to assure achieving the frequency regulation target. The designed interaction game is a single-level game in which EVs are players who determine their charging or discharging strategies in response to the electricity price. A decentralized coordination mechanism of EVs was designed based on game theory to achieve

the optimal performance on providing frequency regulation in a distributed fashion. When considering a large V2G system in which multiple EV aggregators provide V2G regulation services, a non-cooperative two-level game-theoretic framework was proposed (Tan and Wang 2017). In the upper level, the frequency regulation capacity bids among EV aggregators were modeled as a non-cooperative game. Based on the frequency regulation prices obtained from the non-cooperative game, in the lower level, the charging scheduling of EVs was formulated as a Markov game, in which the current move of each EV is only determined by the last moves of the other EVs instead of earlier histories of moves. It is shown that the root mean square value of frequency deviation can be reduced from 0.028 Hz to 0.009 Hz by the proposed approach.

Present: Game-Theoretic Model of Vehicle-to-Grid Regulation

Challenges

Though aforementioned work (Wu et al. 2012; Tan and Wang 2017) proposed solutions to V2G regulation using game theory, there still exist some challenges to be overcome.

- First, Tan and Wang (2017) and Wu et al. (2012) assumed that the strategy set of an individual EV only includes three states, namely, charging, idle, and discharging. This assumption oversimplifies the strategy set of EVs and thus does not consider the case that the strategy set of EVs has infinitely many elements. How to devise an infinite game in which the number of the alternatives available to each player is a continuum becomes a challenge.

- Second, Tan and Wang (2017) and Wu et al. (2012) only considered the decision-making process at each time in V2G regulation, which does not consider the time-coupling effect of the decisions. They may fail to smooth out the power fluctuations of the grid during the whole scheduling period. Therefore, how to incorporate the time-coupling effect of the decisions in the game is a challenge.

- Third, how to devise an optimal pricing scheme of the EV aggregator becomes a challenge. Tan and Wang (2017) and Wu et al. (2012) only studied the benefits of EVs and the utility grid, which fails to consider the optimal pricing scheme of the EV aggregator so as to maximize its utility.

Vehicle-to-Grid Game

To deal with the aforementioned challenges, a dynamic infinite game-theoretic model of V2G regulation is introduced (Chen and Leung 2018). The designed V2G system consists of three components, namely, the grid operator, the EV aggregator, and a fleet of EVs. The V2G system aims at providing frequency regulation services to the power grid through coordinating the charging and discharging schedules of EVs. Meanwhile, EVs are required to be charged to the desired levels. As shown in Fig. 3, the EV aggregator receives regulation request $P_r(t)$ kW from the grid operator at time t and sets its electricity price as $\$p_{EV}(t)$ per kWh. EVs then determine their charging/discharging power in response to the electricity price stipulated by the EV aggregator. Note that, due to the coupling of strategies among EVs, each individual EV also considers the charging and discharging schedules of other EVs when it makes its own schedule. Based on the charging and discharging schedules of EVs, the EV aggregator buys or sells a certain amount of energy traded with EVs, namely, $E_g(t)$ kWh, from or to the grid operator, with the electricity price set in the power grid $\$p_g(t)$ per kWh.

A dynamic infinite game is considered in which the EV aggregator and EVs plan their strategies over the scheduling period $T = \{1, 2, \dots, T\}$. The number of alternatives available to each player is a continuum. Based on the nature of the game, the interaction between the EV aggregator and EVs can be formulated as a non-cooperative game or cooperative game.

In a non-cooperative game, the interaction between the EV aggregator and competitive EVs can be formulated as a Stackelberg game, which is a two-stage strategic game in which the leading decision-maker moves first and then the follow-

**Game Theory Meeting
Vehicle-to-Grid
Regulation: Past,
Present, and Future,
Fig. 3** System model

ing decision-makers move sequentially. In the upper level, EV aggregator acts as the leader who determines the optimal electricity trading price to maximize its own utility, based on the received regulation request. In the lower level, EVs are the followers who determine their charging/discharging strategies based on the price set by the EV aggregator. In order to motivate EVs to provide regulation services, incentives should be given to EVs either explicitly (through paying money for EV's regulation behavior) or implicitly (through devising pricing mechanisms so that EVs can autonomously provide regulation services while responding to the electricity price). In a cooperative game, the EV aggregator and EVs collaborate and come to an agreement to maximize their social welfare. In this sense, EV may not only concern the utility of its own but also consider the social utility (the utilities of all players) when making its strategy. The EV aggregator can give different payments to different EVs based on their behaviors in the game. Some cooperative game theories, such as Shapley value theory (Shapley et al. 1988) and potential game theory (Monderer and Shapley 1996), can be applied to analyze the interactions of players in the V2G cooperative game. Note that an underlying criteria in this cooperative game is that the utility of each player can be improved compared with the non-cooperative game. Otherwise, play-

ers will have no incentive to collaborate in this game.

Future: Research Directions

Based on the current studies on the V2G game, some possible directions are provided for future research.

Hierarchical V2G Game

In the introduced model, only the game between an EV aggregator and its subordinate EVs is considered. Nevertheless, in a large power network which includes aggregators in different levels of the system (Chen et al. 2017), hierarchical game is required to study the interaction among multiple players at different levels. Though Tan and Wang (2017) considered a two-level game in which the interactions among the grid operator, EV aggregators, and EVs were studied, the equilibrium of the game may not be reached. Therefore, it is still an open question how to validate and find the equilibrium in a general hierarchical V2G game.

Imperfect Information Game

To find the Nash equilibrium of the V2G game, EVs generally need to exchange their strategies or some information of their strategies with each

other. In this scenario, this game is a perfect information game in which players know the strategies of other players. When we consider a scenario in which EVs are not willing to share their strategies in the game with others (due to privacy concerns), this game becomes an imperfect information game. How the players find their equilibrium strategies in the imperfect information game is a promising research direction in the V2G game.

Uncertainty in the System

In the designed game, it is assumed that all the system parameters, including the regulation requests, the arrival and departure times of EVs, and the electricity price of the grid, are deterministic when players make their strategies. Nevertheless, in practical operations of the system, there exist uncertainties in these system parameters. For instance, some EVs may depart earlier than their departure times specified at their times of arrivals due to some emergencies. Therefore, how to deal with these uncertainties in the game-theoretic model becomes a challenge. Devising a robust model for the game might be an approach to overcome this challenge.

Acknowledgments This research is supported in part by the Research Grants Council, Hong Kong Special Administrative Region, China (Project No. 17261416).

Game model-aided cooperative spectrum access

Definitions

Cooperative spectrum access technique belongs to spectrum sharing in cognitive radio networks, in which cooperative transmissions may be established between cognitive users (CUs) and primary users (PUs), or between CUs, or between PUs. The application of game theoretic including cooperative and noncooperative ones provides an enhanced spectrum utilization for cooperative spectrum access techniques.

Historical Background

In the very beginning of this century, the blending of cooperative communication technique and cognitive radio (CR) technique emerged as an important approach to improve spectrum efficiency of wireless radio resources. The radio resource is very scarce and is critical to wireless cellular networks and, thus, needs to be intelligently managed and exploited. Nevertheless, as reported in 2008, for the licensed spectrum between 30 MHz and 3 GHz in New York, the maximum occupation rate is about 13%, and the average occupation rate is around 5%. Furthermore, Zhang and Letaief (2008) introduced that the licensed spectrum reported by the Federal Communications Commission (FCC) is largely unoccupied for most of the time in the last decade, which revealed the poor exploitation of radio resources. Specifically, CR techniques allow users to share and employ the available spectrum resources which are not fully used (in time and/or spatial domain), so that the spectrum utilization can be enhanced. In a CR terminology, cognitive users (CUs) normally have the capabilities of spectrum sensing and spectrum accessing for the unoccupied radio resources of primary users (PUs). In particular, the main objective of spectrum access techniques is to enable CUs to coordinate the access with licensed spectrum of PUs. In the turn of this century, cooperative communication became an important technique for wireless systems, and it can enable

one or more nodes to relay information for a direct link by exploiting the broadcast nature of wireless channels, thereby attaining higher communication integrity and enhance channel capacity. Simeone et al. (2007) introduced that, by applying the cooperative communication techniques, it can significantly improve the performance of spectrum access in terms of the opportunity of accessing efficiency. Han et al. (2009) revealed the initial finding that the reliability of the CR networks could be largely improved by the two-hop cooperative spectrum access technique. Later on, Zou et al. (2010) studied the relay selection techniques in the context of multiple-relay CR networks with the aim of improving the performance of the second hop transmission. In recent time Zhang et al. (2014) revealed that, the main consideration in cooperative spectrum access systems was shifted to the reduction of the interference between CUs and PUs.

Foundations

Spectrum sharing in CR terminology can be classified according to different aspects, such as in Fig. 1, including allocation regime and access method. Normally, from the perspective of spectrum allocation, there are non-cooperative and cooperative schemes. Non-cooperative regimes do not require information exchange among PUs and/or CUs, depending on how cooperation is established. As a result, it enables distributed architecture of CR network, thereby having the capability of quick response to dynamic communication environments. Nevertheless, based on limited local information, the non-cooperative approach only results in a degraded performance of spectrum efficiency. On the contrary, cooperative approaches require to share information among all users or mostly among a part of users, which need to keep the cooperation cost as low as possible for the sake of implementation complexity and energy saving. Zhao et al. (2008) investigated an approach to cluster the users and to share the information locally for implementing cooperative spectrum allocation. Compared

to non-cooperative ones, cooperative approaches exploit spectrum more efficiently, resulting in a better fairness among users.

Furthermore, shown by Fig. 1, there are three spectrum access schemes including underlay, overlay, and interwave. In the context of underlay scheme, CUs can employ all the spectrum of PUs to transmit information, subject to the condition that the interference of PUs imposed by CUs is below the tolerated threshold. Note that underlay schemes do not require to perform spectrum sensing. By contrast, for interwave schemes, CUs transmit information simultaneously with PUs only when the busy spectrum slots are detected as spectrum holes. Specifically, CUs can initiate their transmissions by exploiting the available spectrum holes not being in use for most of the time, which improves spectrum efficiency. For most overlay schemes, the cooperation between CUs and PUs can be set up, referring to as cooperative overlay spectrum access, where CUs relay PUs' information by communicating on the available spectrum simultaneously with PUs, as shown by Fig. 2. This is for CUs' payoff, and is obtained from providing the cooperative transmission for PUs, who thereby release some spectrum for CUs' transmission. Compared to underlay schemes, the interference on PUs for the overlay scheme becomes moderate due to the fact that part of the CUs' power is shifted for

cooperative transmission. Giupponi and Ibars (2009) proposed the distributed cooperative approach for the overlay spectrum access systems, where the CUs can opportunistically access the PUs' spectrum by paying a cost for relaying PU's information. By contrast, Jiang et al. (2016) addressed the importance and challenge of knowledge sharing for cooperation between CUs and PUs in overlay spectrum access.

Haykin (2005) first introduced the application of game theory to spectrum sharing and access in CR networks, which can significantly improve spectrum efficiency of overall networks. In a game terminology, it consists of a set of players, each of which is indexed by k , a set of actions or strategies, each of which is denoted by s_k , and the payoff for each player, represented by $\pi_k(\cdot)$. In general, game theoretic techniques are classified into (1) noncooperative games, in which each player motivates to maximize its own utility by making its decision independently, and (2) cooperative games, in which by cooperation all users aim to maximize the total utility. In the majority of game models, it uses the concept of equilibrium, which ensures a player selects the optimal strategy to maximize required utility when the other players' strategies are chosen. Specifically, Han et al. (2012) introduced the definition of Nash equilibrium for CR networks: each player

Game Theory-Assisted Cooperative Spectrum Access, Fig. 1 Classification of spectrum access techniques

Game Theory-Assisted Cooperative Spectrum Access, Fig. 2 Schematic for cooperative overlay spectrum access.

cannot find a better strategy to achieve a higher payoff compared to the current one. Mathematically, the Nash equilibrium can be expressed as

$$\begin{aligned} \pi_k(s_k^*, \mathcal{S}_{K-k}^*) &\geq \pi_k(s_k, \mathcal{S}_{K-k}^*), \\ \forall k &\in \{1, 2, \dots, K\} \end{aligned} \quad (1)$$

where $\pi(\cdot)$ is the payoff conditioned on the strategies employed, s_k^* denotes the Nash equilibrium strategy for player k , and $\mathcal{S}_{K-k}^*$ is the set containing the Nash equilibrium strategies for all the players excluding play k . Note that K is the total number of users.

When applying non-cooperative game models, each user in a cooperative spectrum access system makes the selfish strategy in a distributed manner from its own perspective, which is not optimal from the holistic network-oriented perspective. The most widely used non-cooperative game models include Stackelberg game, auction game, and repeated game. Ouyang et al. (2014) proposed Stackelberg game-based waiting-time reduction approach for the overlay spectrum access systems, in which the CUs playing as relays set up cooperation with the PUs for seeking the admissions of unlicensed access in a period of time. Zhu and Hossain (2015) developed a “leader-and-follower” framework constituted by Stackelberg game model in the overlay spectrum access systems. Specifically, a PU acting as a leader can trade transmission time or power with a CU who acts as a follower for

achieving higher benefits. By contrast, Vassaki et al. (2013) applied the auction game to the overlay spectrum access in CR networks, where the auction activity happened among CUs for bidding the opportunity of relaying the PU’s information. The repeated game is usually referred to as a static noncooperative game and is also known as one-shot game. Nevertheless, the players can update their strategies according to repeating the game for multiple times; in that case, a good mutual payoff among the players may be reached. Niyato and Hossain (2008) introduced a repeated game-based mechanism for tackling the problem of spectrum pricing among PUs for offering accessing opportunities to CUs.

When a cooperative game model is employed, it usually needs a centralized unit which may be acted by one of the users for coordinating the game globally. In contrast to competing in non-cooperative games, users in cooperative games tend to cooperate with each other for the sake of maximizing total utility. In general, the spectrum access problems in CR networks were tackled by leveraging the cooperative game models including coalition games and Nash bargaining. Saad et al. (2009) started the work on using the coalition game in the spectrum access schemes, where the PUs formed a coalition for cooperation instead of competing for CUs’ access, and an increased spectrum efficiency of all PUs was derived. By contrast, El-Bessi et al. (2013) investigated the coalition game theoretic investiga-

tion of the overlay spectrum access problems, in which the CUs were formed into coalitions for cooperation with the objective of maximizing the spectrum efficiency of each coalition. Furthermore, Ma et al. (2015) proposed the coalition game-assisted spectrum access scheme in the CR networks, which motivated to maximize the utilization of available spectrum of both the PUs and CUs by formulating the cooperation among CUs. In the context of Nash bargaining games, by investigating the interaction among users, the actions of the users within a group have strong influences among themselves, so that attaining a good allocation efficiency and fairness. Attar et al. (2009) first invoked Nash bargaining game to the spectrum access mechanism for the traditional cellular networks, where the base station (BS) acting as a central unit can coordinate the spectrum and power resources for PUs and CUs while addressing the fairness issue. More recently, Zhang (2015) proposed a unified analytical framework by leveraging Nash bargaining game to solve the spectrum sharing and access problems in the cognitive small cell networks.

Key Applications

Cooperative spectrum access techniques are fundamental in various CR networks where spectrum sharing between PUs and CUs is required.

[Basic theory of cyberspace security](#)

Definitions

The general theory of information security is to establish a unified basic theory of security within a certain scope.

Historical Background

In the field of information security and cyberspace security, there is no unified security basic theory. And security experts (honkers) have been working on branches of the security field to fight against hackers (Yang et al. 2016a). For instance, honkers have to study cryptographic theory for data encryption in order to prevent hackers from stealing important data; honkers have to study privacy protection technology in order to prevent hackers from stealing personal privacy through big data; honkers have to develop antivirus tools and firewalls in order to resist hackers who create destructive virus and intrude into the system illegally; honkers have to deal with all kinds of hacker's destruction activities: resist network fraud, ensure identity authentication, strengthen security management,

solve disaster recovery problems, master hacker psychology, etc.

In a word, for the areas that are closely related to people's lives, breakers (represented by the hackers) make users all over the world perturbed, especially in the field of Internet, mobile web, e-commerce, etc. so that security experts are always busy with "putting out the fire" all the time, and security field has always been in a state of "take stopgap measures (Yang et al. 2017)."

Cyberspace security has been divided into more than ten branches that look irrelevant. Cybersecurity experts have been forced to become "advanced technicians" to deal with specific problems in different branches. So that no one has the energy to consider the core issues, just like "whether there is a unified basic theory of cyberspace security" and "how to establish such a unified basic theory."

Foundations

The main research content of the general theory of information security is showed as follows: security infrastructure model in cyberspace, security meridian architecture and mechanism of cyberspace, the mesoscopic and macroscopic law of confrontation, game theory in blind and non-blind network confrontation, and the evolution of viruses, rumors, and public opinions (Yang et al. 2018).

- Security infrastructure model in cyberspace

The integrity of the system results from some synergistic effect, which generated by the interaction and interconnection of various elements within the system. Therefore, when multiple security elements and insecurity elements are mixed together, the overall influence of them will increase enormously.

In order to make the overall function of the system develop toward security, it is necessary to coordinate all elements. In the complex system of security (or insecurity), some elements are guiding and dominant, and some elements

are subordinate and dominated. In order to realize the overall security of the system, it is necessary to fully consider the relationship among various elements, strengthening the overall function of security factors and weakening the overall function of “insecurity” factors.

In view of this point, the research about security infrastructure model in cyberspace includes the following: study the “security” closely related to time, study the “security” closely related to objects in finite systems, study the “insecurity events” so as to distinguish “security event” in finite system and give the corresponding mathematical description of “security event,” study the final stability of “insecure” state in finite system based on the second law of thermodynamics, and study and solve the problem of the decomposition and prime decomposition of “insecurity event.”

- Security meridian architecture and mechanism of cyberspace

In reality, it is impossible to directly study “security” in cyberspace, which is a complex giant system (Yang et al. 2016b). Specific insecurity events can be studied to achieve the purpose of studying the “security” problem. In the cyberspace security confrontation, there are almost no concrete structures, such as parallel connection and series connection. Therefore, the “fault tree” and “event tree” in the security engineering are invalid. Traditional Chinese Medicine believes that “human body meridians” exist in the human body system. With the thoughts of Traditional Chinese Medicine, for any insecurity events in cyberspace, security completely unrelated to any specific structure can be studied, such as parallel connection, series connection, etc. With the idea of “divide and conquer,” the meridian architecture and mechanism solve the insecure problem of the small branches and then deal with the larger branches, until the overall insecurity problem is solved.

In view of this point, the research direction of cyberspace meridian architecture and

mechanism includes the decomposition of arbitrary events; the existence of “security meridian map” in limited systems and the corresponding security meridian diagram algorithm; the construction method and mechanism of “meridian map” under the “insecurity incident”; and the application range of the “meridian map” under “security events” in limited system, which includes the function of “fault tree” and “event tree.”

- Mesoscopic and macroscopic laws of confrontation

In past research of cyberspace security, security experts have focused their attentions on the local and microscopic aspects of cyber confrontation, i.e., specific core security technical issues such as encryption, virus, Trojan, and intrusion. In the environment of slow-paced confrontation, these issues are indeed the most important things in the past several decades. However, with the coming of machine hackers, the pace of “machine-to-machine offense and defense” will increase at an exponential rate. To win the initiative of cyber confrontation in the information era, we should not only understand the cyber battlefield from the microscopic view, but also from the perspective of mesoscopic and macroscopic.

In view of this point, the aspects of studying the mesoscopic and macroscopic laws of confrontation are showed as follow. With the help of dissipative structure theory, the mesoscopic description of cyberspace security confrontation can be given, so the promotion effects of the natural degradation of network systems, the attack from hackers, security measures of honkers, etc. to confrontation evolution can be analyzed, and the evaluation of the security situation of the system can be acquired; based on the general equilibrium theory of economics, the macroscopic description of network confrontation problem can be given, so the mathematical nature and operation mechanism of network confrontation problem under the condition of integrated attack and defense can be revealed, and the limitation of cyber capacity between hackers

and honkers on one-on-one confrontation and multiparty confrontation can be studied.

- Game theory in blind and non-blind cyber confrontation

Cyber confrontation is the core content of cyberspace security research field. The blind confrontation of cyber confrontation is that the both sides of attack and defense only know the result of their own assessment and know nothing about the assessment result of the opponent after the fight; the non-blind confrontation is that both sides know the consistent outcome of this round after each round of confrontation. Broadly speaking, cyber confrontation is also a special game. However, for a long time, the professional scholars haven't clearly sorted out the scenes of attack and defense in cyber confrontation and haven't explored the game theory in cyber confrontation (Lei et al. 2017).

In view of this point, the game theory in blind and non-blind confrontation can be studied from the following aspects: study the existence of Nash equilibrium between blind and non-blind confrontation processes from the perspective of game theory; study the relationship between channel capacity and mixed strategy of attack and defense corresponding to Nash equilibrium; and study the fusion of channel capacity, the core of information theory, and Nash equilibrium, the core of game theory. Try to use the multiuser advantage of game theory to make up the multiuser lack in information theory, so as to provide new ideas for basic problems of network information theory that is from information to capacity; study the mutual information between the input and output, the game theory between sender and receiver, the relationship of mutual information between the input and output, and the channel capacity between sender and receiver while the channel is settled.

- The evolution of viruses, rumors, and public opinions

In the cyber war of the information era, three special security attack and defense problems, computer viruses, Internet rumors, and public opinions, will attract more and

more academic attention. Computer viruses can be said to be one of the most core security issues in cyberspace, all kinds of malicious codes just like biological viruses; they cannot be exterminated and cost a large amount of resources; however, Internet rumors are regarded as one of the most lethal weapons in future information warfare by cybersecurity experts; moreover, there is no previous experience to learn and we must rely on our own efforts. Election-related public opinion is a new weapon in the cyber warfare; with the rapid development of "we-media," it will be more and more lethal to a certain kind of country. Therefore, these security methods must be systematically studied, and their corresponding research methods can be extended to other security fields.

In view of this point, the evolution of viruses, rumors, and public opinions can be studied from several aspects: study the transmission dynamics of several types of viruses (e.g., death virus, rehabilitation virus, and immune virus); study the effects of several prevention measures, analyze the situation of latent virus, and explore virus mechanisms and prevention mechanisms; study the dynamics of rumor under the situations of single institution and multiple institutions; study the dynamic equations of public opinion structure and the steady-state solutions of several kinds of public opinion equations; and reveal the evolution rules of viruses, rumors, and public opinions.

Key Applications

The general theory of information security tries to stipulate corresponding security implications and establish a unified security foundation theory within a certain scope. It makes a quantitative discussion on security confrontation in cyberspace, comprehensively and systematically. The general theory of information security aims to reveal some basic rules of hackers' attack and defense and security evolution and applies them to the main branches of cyberspace security.

Group Key Agreement for Wireless Networks

Technology, Nanjing, China

Synonyms

[Multiparty key agreement for wireless networks](#)

Definitions

Group key agreement is the protocol whereby multiple parties can agree on a common key, which ensures secure information transmission in their later communication. That is, the negotiated common key can be used to encrypt message for communicating parties. Protocols that are useful in practice do not reveal the negotiated common key to any eavesdropping parties.

In wireless networks, group key agreement refers to a group of m trusted nodes that aim to agree on a common secret key K over a wireless channel. Note that the communication channel for agreeing on the common secret key K is insecure. That is, the communication channel can be controlled by an adversary. In general, there are two types of adversaries: passive adversary and active adversary.

1. **Passive adversary:** A passive adversary tries to learn information about the common secret key by eavesdropping on the communication channel.
2. **Active adversary:** An active adversary attempts to impersonate other party or disrupt the protocol by altering, injecting, intercepting, and replaying messages.

The goal of group key agreement is to agree on a common secret key without revealing the common secret key to any adversaries.

Historical Background

Diffie-Hellman protocol (Diffie and Hellman 1976) is the first modern key agreement protocol, which is proposed in 1976. But this protocol can only support two parties. By using Weil pairing, Joux proposed the three-party key agreement protocol (Joux 2000). Note that this protocol requires only one round to derive the common secret key among three parties.

In order to generate the common secret key among multiple parties, Steiner et al. proposed the key agreement protocol (Steiner et al. 2000), which supports multiple parties and

considers dynamic change among these parties. However, this protocol needs $n + 1$ rounds to generate the common secret key. In addition, the communication and computation overhead are relatively large. Here, n is the number of parties. Based on Joux's protocol, Barua et al. proposed the multiparty key agreement protocol (Barua et al. 2003). In this protocol, a tree structure is employed to help multiple parties to agree on a common secret key. Note that for n parties, it requires $n \lceil \log_3 n \rceil$ rounds to derive the common secret key. And the communication and computation overhead are reduced compared with Steiner et al. (2000). Later, Shen et al. proposed the group key agreement protocol (Shen et al. 2018) that aims to reduce the communication overhead and the number of rounds for generating the common secret key. In particular, the communication overhead and the rounds of the protocol are $n\sqrt{n}$ and 2, respectively.

The above group key agreement protocols are interactive key agreement protocols. Namely, each party requires to interact with other parties to derive a common secret key. Compared with interactive key agreement protocol, noninteractive key agreement protocol is the other kind of key agreement protocol, where multiple parties can agree on a common secret key without interacting with others. In 2003, by using the concept of multilinear maps, Boneh and Silverberg presented a multiparty noninteractive key agreement protocol (Boneh and Silverberg 2003), whereas it was not until 2013 that the constructions for multilinear map was designed by Garg, Gentry, and Halevi using ideal lattices (Garg et al. 2013). Meanwhile, Coron, Lepoint, and Tibouchi also presented the constructions for multilinear map over integers (Coron et al. 2013) at the same year. However, it is pointed in Boneh and Zhandry (2017) that both Garg et al. (2013) and Coron et al. (2013) require a secure setup for key agreement purpose. By using the concept of indistinguishability obfuscation and the constrained pseudorandom functions, Boneh and Zhandry designed the noninteractive key agreement protocol that requires no trusted setup.

Foundations

Security assumptions and adversarial model are two essential foundations for group key agreement in wireless networks. For one thing, the security of the protocol can be deduced from security assumptions. For another thing, the security level of the protocol depends on the strength of the adversarial model that is defined previously. In the following, some security assumptions and a well-known adversarial model of group key agreement are presented.

1. Security assumptions.

- (a) Decisional Diffie-Hellman (DDH) assumption: For a group G of order q , the DDH assumption says that the following two tuples is computationally indistinguishable.

$$\begin{cases} R = (g, g^x, g^y, g^z) \in G^4 \\ D = (g, g^x, g^y, g^{xy}) \in G^4 \end{cases}$$

Here, g is the generator of G , and $x, y, z \leftarrow_R \mathbb{Z}_q$.

- (b) Computational Diffie-Hellman (CDH) assumption: For a group G of order q , the CDH assumption states that given

$$g, g^x, g^y$$

it is hard to compute

$$g^{xy}$$

Here, g is the generator of G , and $x, y \leftarrow_R \mathbb{Z}_q$.

- (c) Bilinear Diffie-Hellman (BDH) assumption: For groups G_1 and G_2 of order q , the BDH assumption states that given

$$g, xg, yg, zg$$

it is hard to compute

$$\hat{e}(g, g)^{xyz}$$

Here, g is the generator of G_1 , and $x, y, z \leftarrow_R \mathbb{Z}_q$.

2. Adversarial model. The capabilities and possible actions of the attacker can be reflected by the adversarial model. One of the famous adversarial models is the unauthenticated links model (Canetti and Krawczyk 2001), which is described as follows.

- (a) Basic capabilities: Basic capabilities of the attacker include listening to all the transmitted information, controlling the transmission way of the messages, changing messages, or injecting messages.
- (b) Obtaining secret information: Attacker can access secret information of parties. According to the type of information that can be accessed by the attacker, three categories of information leakage are summarized as follows.
- (i) Session-state reveal.
 - (ii) Session-key query.
 - (iii) Party corruption.

In addition to the above capabilities provided for the attacker, session expiration is also an important element of the adversarial model. That is, the value of the expired session key can no longer be revealed by the attackers. Note that it is the foundation for the notion of perfect forward secrecy in key agreement.

Applications

The group key agreement is used to establish a common secret key such that the communications among multiple parties encrypted with this key are protected from the attacks of adversaries. In particular, the generated common secret key can be used for encrypting messages among multiple nodes in wireless networks. Note that the common secret key hold by multiple nodes supports the symmetric encryption for the message, which is more efficient than asymmetric encryption and has wide applications in wireless networks.

Definitions

Communication-based train control (CBTC) system is an automated control system for railways that ensures the safe operation of rail vehicles using wireless data communications. It can maximize the utilization of railway network infrastructure and enhance the level of safety and service offered to customers. The train-ground

communication system is one of the key sub-systems of CBTC. A seamless handoff scheme based on SCTP and IEEE 802.11p is proposed to provide high link availability in CBTC systems. Stochastic semi-Markov decision process (SMDP) has been successfully used to solve finance and admission control problems, among others. This article focuses on the application of SMDP to the handoff decision problem in CBTC systems. Maximizing the SCTP throughput and minimizing the handoff latency are the objectives in the handoff decision phase.

Historical Background

Communications-based train control (CBTC) systems is an automated train control system using continuous, high capacity, and bidirectional train-ground communications to ensure the safe operation of rail vehicles (Pascoe and Eichorn 2009). It can maximize the utilization of railway network infrastructure and enhance the level of safety and service offered to customers. As numerous CBTC systems are in operation around the world, CBTC is becoming more and more popular as an advanced train control system.

CBTC systems have stringent requirements for wireless communication availability and latency. Whereas in commercial wireless networks, less service availability means less revenues in CBTC systems, less service availability could cause train derailment, collision, or even catastrophic loss of life

or assets. Therefore, although it may not be necessary to have continuous communications between the train and ground, it is important that the radio links are available when they are needed and the latency is minimized. Furthermore, it is important to maintain this availability and quick response time, while a train is moving at high speed.

Most existing WLAN-based train-ground systems are using traditional IEEE 802.11 technologies, such as 802.11a/b/g. However, IEEE 802.11a/b/g WLANs were not originally designed for high speed environments. Particularly, when a train moves away from the coverage of a WLAN access point (AP) and enters the coverage of another AP along the railway, a handoff procedure occurs, and this handoff process may result in communication interrupt and long latency (Mishra et al. 2003).

There are numerous handoff schemes proposed in the literature to decrease WLAN handoff latency (Mishra et al. 2003; Ramani and Ramani 2005) in data link layer, but most of them require coordination/cooperation between APs and mobile clients, which may make it difficult to implement them in CBTC systems.

The seamless handoff management problem can also be solved at transport layer. Stream Control Transmission Protocol (SCTP) (Ma et al. 2004), a new IETF-standardized transport layer protocol in addition to Transmission Control Protocol (TCP) and User Datagram Protocol (UDP), is commonly used to solve the handoff management problem. As a protocol with the features of the multi-homing, multi-stream, and partial reliable data transmission, SCTP are especially attractive for applications that have stringent performance and high reliability requirements. Compared to the data-link-layer handoff management approaches, transport layer schemes have many advantages, such as improved throughput and latency performance. Moreover, no third party other than the endpoints participates in handoff process, and no modification or addition of network components is required, which makes transport layer approaches attractive in WLAN-based CBTC systems, where commercial-off-the-shelf equipments are widely used.

Although some works have been done for handoff management, most of the works are about general commercial wireless system, which is different from the CBTC train-ground communication system.

In this article, we propose a seamless handoff scheme for CBTC train-ground communication system based on SCTP and IEEE 802.11p, which is an emerging technology for vehicular communication networks. To the best of our knowledge, the design of seamless handoff scheme based on SCTP and IEEE 802.11p has not been done in previous works. The distinct features of the proposed scheme are as follows.

- (1) We propose a seamless handoff scheme based on SCTP and IEEE 802.11p to provide high link availability in train-ground communication systems.
- (2) The handoff decision problem is formulated as a stochastic semi-Markov decision process (SMDP), which has been successfully used to solve finance (Feinberg and Schwartz 2002) and admission control (Yu et al. 2006) problems, among others.
- (3) The simulation results show that the proposed scheme can significantly improve SCTP throughput and achieve seamless handoff in train-ground communication system.

Proposed Train-Ground Communication System Based on SCTP and IEEE 802.11p

Overview of Communication-Based Train Control and Its Train-Ground Communication System

Figure 1 gives a simple view of a CBTC system with WLAN-based train-ground communication system. In this system, continuous bidirectional wireless communications between each station adapter (SA) on the train and the wayside access point (AP) are adopted instead of the traditional fixed-block track circuit. The railway line is usually divided into areas. Each area is under the control of a zone controller (ZC) and has its

own wireless transmission system. The identity, location, direction, and speed of each train are transmitted to the ZC. The wireless link between each train and the ZC must be continuous to ensure the ZC knows the location of all the trains in its area at all times. The ZC transmits to each train the location of the train in front of it; a braking curve is given to enable it to stop before it reaches that train as well. Theoretically, two successive trains can travel together as close as a few meters in between them, as long as they are traveling at the same speed and have the same braking capability.

Train-ground communication systems are primarily designed to connect each component of CBTC systems: zone centers (ZCs), access points (APs) along a railway, and train aboard equipment. A basic configuration of a WLAN-based train-ground communication system is shown in Fig. 1. Following the philosophy of open standards and interoperability, the backbone network of the train-ground communication system includes Ethernet switches and fiber-optic cabling that are based on the IEEE 802.3

standard. The wireless portions of the train-ground communication system, which consist of APs along the railway and SAs on the train, are based on the IEEE 802.11 standard.

When a train moves away from the coverage of an AP and enters the coverage of another AP along the railway, the handoff procedure may result in communication interrupt and long latency. In CBTC systems, it is important to maintain communication link availability in order to guarantee train operation safety and efficiency. To this end, we present a seamless handoff scheme based on SCTP at transport layer and IEEE 802.11p to provide high link availability in CBTC systems.

The Proposed Train-Ground Communication System Based on SCTP and IEEE 802.11p

Figure 2 describes the system architecture and protocol stack of the proposed train-ground system based on SCTP and IEEE 802.11p. There are two radios in the SA on the train. Each radio

H

Handoff Management in Wireless Communication-Based Train Control Systems, Fig. 1 A communication-based train control (CBTC) system

Handoff Management in Wireless Communication-Based Train Control Systems, Fig. 2 System architecture and protocol stack of the proposed train-ground communication system based on SCTP and IEEE 802.11p

is related to a different MAC interface and IP interface. The ZC also has two IP interfaces.

Normally only one pair of IP addresses (the IP address in the ZC and the IP address in the SA) is working, which is called the primarily path. When a handoff is triggered, the SA on the train will try to exchange necessary information with the ZC to establish another path with the other radio, which is called the secondary path. When the second path is established, the communication nodes copy all the buffered data from the primary path to the second path so that the data in sending buffers of the two paths are completely the same. The SA also needs to cut off the primary path to finish the handoff process at an appropriate time. The whole handoff procedure is shown in Fig. 3.

A critical issue in the above train-ground communication system is the handoff decision policy, i.e., when to perform handoff. In high speed environments, wireless channels are changing dynamically in CBTC systems. If the handoff decision policy is not designed carefully, communication interrupt and long latency may occur, which will significantly affect

the performance of a CBTC system. Therefore, an efficient handoff decision policy is needed to decide at what time the second path should be established and when to cut off the primary path, which will be studied in the following section.

Optimal Handoff Decision Policy in the Train-Ground Communication System Based on SCTP and IEEE 802.11p

An SMDP model consists of the following five elements: (1) decision epochs, (2) states, (3) actions, (4) rewards, and (5) transition probabilities, which will be described in the following.

Action and State

In our SMDP model, at each decision epoch, the SA on the train has to decide whether the connection should use the current chosen AP or connect to the next AP (we assume the SA on the train won't be in the coverage of three successive APs).

Handoff Management in Wireless Communication-Based Train Control Systems, Fig. 3 The proposed handoff procedure

Each state has the following information:

1. The measured signal noise ratio from two APs;
2. The current SCTP congestion window;
3. The path(s) currently used by the SA;

Reward Function

In our formulation, we define the reward function as the combination of SCTP throughput and delay. This is a common approach used in the optimization literature, which is called Aggregate Objective Function (AOF), to solve an optimization problem with multiple objectives. In reality, different CBTC networks have different throughput and packet delay requirements. By adjusting the parameters in the reward function, the proposed scheme is generic enough to accommodate different requirements in real CBTC networks.

State Transition Probability

In CBTC systems, due to the restrictions of railways and trains, the ground antenna cannot be installed too high. The low antenna height means that the Fresnel zone typically limits the propagation of radio to fairly short ranges.

In this paper, we use finite-state Markov channel (FSMC) models in CBTC systems.

FSMC models have been widely accepted in the literature as an effective approach to characterize the correlation structure of the fading process, including satellite channels, indoor channels (Babich and Lombardi 1997), Rayleigh fading channels (Wang and Chang 1996), and Nakagami fading channels (Iskander and Mathiopoulos 2003). Considering FSMC models may enable substantial performance improvement over the schemes with memoryless channel models (Yang et al. 2005).

In FSMC models, the range of the received SNR can be partitioned into discrete levels. Each level corresponds to a state in the Markov chain. Assume there are L states in the model. Let i and γ denote the instantaneous channel state and SNR, respectively. When the channel is in state i , the corresponding SNR is γ_i . Then we have $\gamma_i < \gamma < \gamma_{i+1}$, $1 \leq i \leq L - 1$. The probability of transition from state i to state j in the Markov model is denoted by $P_{i,j}$.

In real systems, the values of the above transition probability can be obtained from the history observation of CBTC systems.

In order to derive the congestion window transition probability, we refer to the SCTP behavior model in Ma et al. (2007). The SCTP behavior is modeled in terms of "rounds," where a round starts when the sender begins the transmission of

a window of chunks and ends when the sender receives the last acknowledgment for chunks in this window. SCTP essentially doubles its congestion window size in the slow-start stage and increases the congestion window linearly in the congestion avoidance stage if none of the chunks in the previous window is lost during the previous RTT . If one or more chunks in the previous window are lost, the congestion window is set to half of the current window. The congestion window will not change until all the chunks in the window are sent out.

Given the current congestion window η , when SCTP is in slow-start, the congestion window in the next epoch can be η , $\eta/2$, or 2η . For the congestion avoidance stage, the congestion window can be changed to η , $\eta/2$, or $\eta + 1$, which depends on the decision epoch and packet losses.

Optimality Equations and Value Iteration Algorithm

The optimality equation for an SMDP is given by Puterman (1994):

$$v(s) = \max_{a \in A} \left\{ r(s, a) + \sum_{s' \in S} \lambda P[s'|s, a] v(s') \right\}, \quad (1)$$

where $v(s)$ denotes the maximum expected total reward, given the initial state s , and s' represents next state. That is

$$v(s) = \max_{\pi} v^{\pi}(s). \quad (2)$$

The solutions of the optimality equation correspond to the maximum expected total reward $v(s)$ and the SMDP optimal policy δ^* . Note that the SMDP optimal policy δ^* indicates the decision as to which action to choose.

We use value iteration algorithm (VIA) in this paper to determine a stationary deterministic optimal policy and the corresponding expected total reward.

Simulation Results and Discussions

In this section, simulation examples are used to illustrate the performance of the proposed handoff scheme based on SCTP and IEEE 802.11p. We compare the handoff delay in the proposed scheme with that of existing handoff scheme based on UDP and traditional IEEE 802.11. The results show that the handoff delay is very close to zero in the proposed scheme. In addition, the simulation results show that the proposed SMDP based optimal handoff policy can significantly improve SCTP throughput in CBTC train-ground communication systems.

Figure 4 shows the sequence numbers of the packets at the corresponding time on the X axis. From this figure, we can see that, in the traditional UDP and 802.11 based handoff scheme, the SA on the train cannot have communication with any of AP in a period of time, and the packet sent in that period of time is lost which is unacceptable for real-time and safe required applications. This is caused by the handoff delay in the traditional handoff scheme, in which the old path is broken before the new path is setup to the new AP.

Comparatively, it is evident that the proposed handoff scheme supports seamless handoff between adjacent APs. During the handoff process, the SA associates to the new AP with the other radio, obtains a new IP address from the old path, and communicates with the new address before the old path is terminated. No packets are lost during this seamless handoff procedure. The slight delay in the handoff process is caused by the information exchange before the establishment of the new path.

We compare the performance of our proposed handoff decision policy, with the other two heuristic handoff decision policies. For the first heuristic policy, the path to be selected in each decision epoch is the one that always has the better SNR. For the second heuristic policy, we also model the handoff decision as a SMDP, but SCTP congestion window variation is not considered in this model.

The SCTP throughput improvement is shown in Fig. 5. The SCTP throughput increases with the weight factor for our proposed

Handoff Management in Wireless Communication-Based Train Control Systems, Fig. 4 Packet sequence number in different schemes

Handoff Management in Wireless Communication-Based Train Control Systems, Fig. 5 The throughput under three policies with different weight factor

policy; that is because the policy is designed to get more throughput when weight factor increases. Similarly, the two heuristic policies give unchanged worse throughput performance compared to our proposed decision policy when weight factor increases; this is because these two policies don't care too much about

SCTP congestion window variation which is a very important information for throughput. Particularly, when the weight factor decreases to zero, our proposed decision policy is not designed to get the best SCTP throughput, which gives the same throughput performance as one of the heuristic policies.

Definition

A handoff in IP networks is the process by which a mobile node changes its point of attachment from one network to another network while maintaining IP communication sessions (Lee et al. 2013a). Without the IP handoff support for the mobile node, all ongoing IP communication sessions are disrupted by the change of point of attachment. To support a seamless handoff in IP networks, specially designed network entities and protocols are required, and those have been developed for IPv4 networks and IPv6 networks separately.

Historical Background

As the handoff of a mobile node in IP networks is related to network entities and protocols for the Internet, the Internet Engineering Task Force (IETF) are taking the lead to development of specifications for the seamless handoff. The IP handoff support for IPv4 called Mobile IPv4 (MIPv4) was first specified in RFC 3344 and obsoleted by RFC 5944. The IP handoff support for IPv6 called Mobile IPv6 (MIPv6) was first specified in RFC 3775 and obsoleted by RFC 6275. Such host-based mobility management protocols (i.e., MIPv4 and MIPv6) assume that a mobile node is capable to signal to the network entities that the mobile node changes its point of attachment from one network to another network. This assumption does not hold for all cases especially for lightweight mobile devices such as small sensors and mobile phones. Proxy Mobile IPv6 (PMIPv6) specified in RFC 5213 was developed to solve this issue as a network-based mobility management protocol. Network entities detect the IP handoff of a mobile node and provide required operations for IP session continuity in PMIPv6.

The IP handoff directly affects the user quality of experience (Pack et al. 2007). A long handoff latency results in a high packet loss and thus causes poor quality of experience. In addition, depending on a mobility management

protocol, the required operational cost for the IP handoff support is different. Accordingly, various extensions of the mobility management protocols have been specified by the IETF, e.g., fast handover, route optimization, and hierarchical mobility management extensions. Also, various improvements have been suggested from researchers over years.

Key Points

The IP handoff is commonly evaluated with the following performance criteria:

- Handoff latency: It is the time interval during which a mobile node cannot send or receive any packets, while it changes its point of attachment from one network to another network (Lee et al. 2013a).
- Handoff blocking probability: It is the probability which a mobile node cannot complete its handoff when the network residence time is less than the handoff latency (Lee et al. 2013a).
- Packet loss: It is the sum of all lost packets destined for a mobile node during the mobile node's handoff (Lee et al. 2013a).
- Signaling cost: It is the accumulative signaling overhead for the IP handoff support (Lee et al. 2010).
- Packet delivery cost: It is the accumulative traffic overhead caused by packet delivery on the routing path for the IP session continuity (Lee et al. 2010).

For calculating the handoff latency, a timing diagram of the handoff is required, and owing to the operational differences, each mobility management protocol presents different timing diagrams for the IP handoff support. For instance, the handoff latency for MIPv6 is the sum of the link-layer handoff latency, the movement detection latency at the network layer, the duplicate address detection latency, and the location registration latency, whereas the handoff latency for PMIPv6 is the sum of the link-layer hand-

off latency and the location registration latency. Also, fast handover extensions further minimize the handoff latency by performing IP handoff required operations in advance.

The handoff blocking probability and the packet loss are proportional to the handoff latency as expected. The higher handoff latency is essentially a trouble resulting in poor performance which must lead to poor quality of experience for users.

The signaling cost is calculated as the product of the size of signaling message for the IP handoff support and the hop distance between the signaling message source and destination. The required signaling messages and the hop distance are different with mobility management protocols. As extensions are applied to the basic mobility management protocols like MIPv6 and PMIPv6, the protocol complexity increases and the signaling cost thus increases.

The packet delivery cost is calculated as the product of the data packet size and the hop distance between the data packet source and destination. The hop distance is different with mobility management protocols.

Key Applications

The understandings of the IP handoff support and related performance criteria are important when we choose an appropriate IP mobility management protocol for a given condition. Those are also required when we design new IP mobility management protocols.

Future Directions

The initial approaches for the IP handoff support such as MIPv4, MIPv6, and PMIPv6 were developed based on centralized mobility anchors that facilitate the IP handoff support for mobile nodes in a highly efficient manner. When those mobility management protocols were developed, mobile network architectures were in centralized hierarchical forms. The deployment of such centralized mobility anchors in the centralized

hierarchical forms was thus considered. However, due to rapidly increasing Internet traffic, the mobile network architectures are being changed toward flat mobile network architectures in 5G. The new approach called distributed mobility management is thus being considered for the flat mobile network architectures in 5G (Lee et al. 2013b). The IP handoff support is yet the main key for distributed mobility management (Ko et al. 2016).

Definitions

- *Long-term evolution in unlicensed band (LTE-U):* LTE-U means that the 4G radio communications technology (i.e., LTE) is used in unlicensed spectrum such as the 5 GHz band, which is already used by 802.11 equipment.

Historical Background

To deal with the growing mobile data traffic, many researchers have paid attention to LTE-U (Huawei 2014; Qualcomm Technologies 2014). By extending an LTE network architecture to unlicensed spectrum and aggregating licensed spectrum and unlicensed spectrum by the carrier aggregation technique (Zhang et al. 2015), it is anticipated that LTE-U can efficiently mitigate the explosive mobile data traffic. However, the regulation in unlicensed spectrum should be complied to exploit unlicensed spectrum. The detailed regulations for using unlicensed spectrum are different according to countries. These regulations can be summarized as follows (3GPP 2015):

- *Transmission power:* LTE can control transmission power in unlicensed spectrum. In addition, the transmission power should be limited to the maximum value.
- *Location:* LTE can use unlicensed band for indoor only or both indoor and outdoor.

- *Dynamic frequency selection (DFS)*: LTE-U should apply the DFS mechanism designed to avoid causing interference to a non-international mobile telecommunication system (e.g., radar).
- *Listen before talk (LBT)*: LTE-U should apply the LBT mechanism for fair co-existence with other wireless communication systems (e.g., Wi-Fi).

In the United States of America and Korea, LBT implementation is not mandated to be used in unlicensed spectrum. Therefore, any device can access unlicensed spectrum without the LBT mechanism (i.e., clear channel assessment (CCA)) in those countries. On the contrary, in Europe and Japan, there is a mandatory requirement to implement LBT when accessing unlicensed spectrum. That is, when any device in those countries tries to access unlicensed spectrum, the device should conduct CCA beforehand. If the sensed energy level of unlicensed spectrum is lower than a certain threshold, the device can access the unlicensed band.

Due to the different regulations among countries, two types of LTE in unlicensed band have been proposed: (1) LTE-U and (2) Licensed Assisted Access (LAA). These are described as follows (4):

- *LTE-U*: LTE-U is proposed by Qualcomm and developed by the LTE-U forum. Many major companies such as Verizon, Ericsson, Qualcomm, and Samsung are included in this forum. Originally, LTE-U was designed for countries that do not have LBT regulation (e.g., the United States of America and Korea). LTE-U uses licensed spectrum as the primary carrier component for both control channel and data channel, whereas unlicensed spectrum is used only as the secondary carrier component to deliver data.
- *LAA*: LAA has been standardized by the 3GPP in Rel-13. The goal of LAA standardization is a unified global framework that complies with the regulation in the different regions of the world. Therefore, LAA is designed to satisfy the LBT requirement, which is mandated in some countries. Similar as LTE-U, LAA also uses licensed spectrum as the primary carrier component for signaling and delivering data, whereas the unlicensed spectrum is exploited as the secondary carrier component that is added to the primary carrier component by means of a carrier aggregation.

The detailed comparison between LTE-U and LAA is summarized in Table 1 (4).

Handover in LTE-U/LAA, Table 1 Comparison between LTE-U and LAA

Classes	LTE-U	LAA
Developed by	LTE-U forum	3GPP
Frequency bands	5150–5250 MHz and 5725–5850 MHz, whereas 5250–5725 MHz has been reserved for future use	5150–5925 MHz
Mode of operation	Supplemental downlink only	Downlink and up-link
Bandwidths allowed	20 MHz	10 and 20 MHz
Purpose	Use of the existing LTE specifications in countries that do not impose LBT	Single unified global framework that complies with regulations in the different world regions
Coexistence mechanisms	Carrier selection, on-off switching, carrier sensing adaptive transmission (CSAT)	Carrier selection and LBT
Main advantage	Will likely be the first version in the market	Will be a single unified global framework for LTE in unlicensed bands worldwide

Foundations

Since LTE-U/LAA aggregates licensed and unlicensed spectrum, there are several benefits compared to a Wi-Fi system, which can be summarized as follows (Zhang et al. 2015):

- *Significant boost in data rates:* Since LTE-U/LAA can use the carrier aggregation technique to aggregate licensed and unlicensed bands, higher throughput can be achieved. LTE-U/LAA is a synchronous system and adopts scheduling-based channel access, whereas Wi-Fi system applies contention-based random access. Therefore, higher spectrum efficiency (i.e., higher throughput) is guaranteed in an LTE system. Furthermore, multi-device frequency-selective diversity gain can be achieved based on the feedback of channel quality indicator (CQI) from devices.
- *Reliable and secure communication:* In LTE-U/LAA, the primary carrier component where control messages are transmitted is always set to licensed spectrum. This means that the control messages are exchanged properly between base station and devices regardless of unlicensed spectrum conditions. In addition, LTE-U/LAA has better authentication and authorization techniques than a Wi-Fi system, which provides more secure transmissions.
- *Seamless mobility and coverage:* In LTE-U/LAA, devices can access both licensed and unlicensed spectrum by the same LTE access procedures (e.g., integrated authentication and security). Moreover, the primary carrier component in licensed spectrum can always provide ubiquitous coverage. Therefore, when devices move out of the coverage of a base station, only the horizontal handover procedure (between same systems) is needed, and therefore the device's ongoing session can be switched as seamlessly as possible without any interruption.

Although LTE-U/LAA has quite a lot of advantages, LTE-U/LAA is still facing many challenges. One of the challenges is the mobility management. The handover procedure in the

original LTE networks is designed for the handover within licensed spectrum and can be explained as follows:

The handover procedure in the original LTE networks is divided into three phases (i.e., handover preparation phase, handover execution phase, and handover completion phase). In the original LTE networks, the UE periodically measures the radio signal strength of the neighbor cells and source cell. Then, the UE reports the strength information to its serving evolved node B (eNB) by using a Measurement Report message. If the signal strength of a certain neighbor cell is stronger than that of the serving cell, the serving eNB decides to execute the handover and initiates the handover preparation phase.

In the handover preparation phase, the source eNB sends a Handover Request message to the target eNB that has the strongest signal strength to the UE. When the target eNB receives the Handover Request message, the target eNB allocates a radio resource for the UE and replies a Handover Request ACK message to the source eNB. After receiving the Handover Request ACK message, the source eNB triggers the handover execution phase by sending a Radio Resource Control Connection Reconfiguration message to the UE.

In the handover execution phase, the UE disconnects from the source eNB and synchronizes to the target eNB. When the UE completes synchronization (e.g., random access process to associate the target eNB), the UE informs the target eNB by sending a Radio Resource Control Connection Reconfiguration Complete message, and the target eNB replies to the UE with an ACK.

Finally, in the handover completion phase, the path to the target eNB from the source eNB is switched in the LTE core network. When the path switch procedure is completed, the source eNB releases the UE context.

Since the handover procedure in the original LTE networks is designed for the handover within the licensed spectrum, if it is applied for the handover between licensed and unlicensed spectrum without any modification, the handover

performance can be degraded. When the UE is associated with the serving eNB and the conventional handover procedure is triggered to the target eNB with the unlicensed band, the delay of handover execution phase should be longer than that of the conventional handover with the licensed band. Since the other systems share the unlicensed band, the target eNB waits to access the unlicensed band until the other systems do not access the unlicensed band. Therefore, due to this additional delay, the overall delay of handover with the unlicensed band can be longer than that of the handover with the licensed band.

Lee et al. (2015) evaluated the handover performance of LTE-U/LAA in terms of TCP goodput by means of the NS-3 simulator with a modified LENA LTE module with the handover procedures in the original LTE networks. The evaluation result showed the degradation of the handover performance when the conventional handover procedure was applied without any modification.

In the simulation, specifically, the performance evaluation is conducted in two scenarios as shown in Fig. 1. In scenario 1, LTE evolved node B (eNB) and LTE-U access point (AP) transmit data through licensed spectrum (f1)
